Fig. 51-4 A and B, This 9-year-old boy had an amputation of his left thumb at the midproximal phalanx level. C-E, The thumb was reconstructed with a left trimmed great toe transfer with excision of the medial portion of the proximal and distal phalanges of the great toe. F, The donor site in the left foot. G and H, The trimmed toe transfer has excellent function and appearance similar to that of a thumb.

A child with a hypoplastic or absent thumb but normal fingers should be considered for pollicization of the index finger. Toe transfers have been described for the treatment of isolated thumb hypoplasia⁵² but the benchmark is pollicization of the index finger.^{22,26,40-41,44,52-53} However, in congenital constriction ring syndrome in which the thumb is absent distal to the carpometacarpal joint, the proximal structures are normal, and the child will benefit more from a toe-to-thumb transfer (Fig. 51-5).

Fig. 51-5 A and B, This 3-year-old girl had congenital constriction ring syndrome affecting her right thumb, index finger, and middle finger. The thenar muscles were normal. C and D, She underwent a right second toe-to-thumb transfer. Her right great toe was abnormal, and she had a left above-knee amputation because of the congenital constriction ring syndrome. (The red line indicates the first dorsal metatarsal artery, the blue markings are the dorsal subcutaneous veins, and the black markings are the surgical incisions.) E and F, The postoperative functional result and a comparison of the appearance of the toe transfer with the contralateral thumb.

The choice of using a great toe or a second toe transfer should be individualized. Various toe transfers have been reported; however, the most appropriate one to transfer for each anomaly is controversial. Although a great toe transfer for thumb reconstruction may produce the most functional and aesthetically pleasing result (see Fig. 51-4), most parents choose the second toe for transfer in children.⁶² The donor site defect is much more obvious after a great toe transfer compared with the donor site after a second toe transfer. Because most parents have difficulty with their decision to “mutilate” a normal foot,²⁶ even if it means providing improved function to the hand, they tend to choose a second toe transfer because of the less obvious donor-site defect (see Figs. 51-2 and 51-3). Concerned families can be advised that parents and children are very accepting of the donor-site defect after second toe transfer, and this is true even as children enter adulthood.⁶³⁻⁶⁵ Patients prefer a second toe transfer in cultures in which thong-type sandals are worn, because the thong remains positioned between the great and third toes. After a great toe transfer, weight-bearing is shifted underneath the second and third metatarsal heads but does not necessitate modified footwear.⁵⁰ In general, parents can be reassured that sports activities are not significantly affected by second toe transfers; however, impairment in push-off and running speed and difficulties walking on uneven or sloped surfaces have been documented after great toe transfers.^{20,66-69}

Although it is technically possible to perform a toe transfer in patients younger than 1 year of age, most authors recommend waiting until they are 18 months of age, when the anesthetic risk is lower and the size of the digital vessels is somewhat larger.^{17,18,20} Children begin to use their hands during the first year of life; however, most authors agree that successful cortical reintegration can occur up to the age of 3 years and possibly even later.^{12,37,70} Waiting longer allows the family ample time to make an informed decision about the need for reconstructive surgery. Late toe transfers in children older than 10 years of age have been reported; however, even though the toe survives, children older than 8 years of age do not achieve normal sensibility in the transferred toe.⁷⁰ Parents should be counseled that the likelihood of cortical reintegration may be better if the procedure is performed when their child is younger.^{14,33,51,70}

Toe transfers have been used to reconstruct traumatic injuries in children and adolescents.⁵¹ Indications include thumb amputations (see Figs. 51-2 and 51-4), multiple finger amputations (see Fig. 51-3), metacarpal hand reconstruction, joint reconstruction, and pulp loss for insensibility.^{12,42,51} Toe transfers for trauma are usually performed later, after amputations have healed and parents have had time to decide, but an immediate toe transfer is very rarely considered for reconstruction of a degloved thumb with an intact bony skeleton and flexor and extensor tendons.

For microsurgical thumb reconstruction, second toes are used for children whose parents do not like or cannot tolerate loss of the great toe, for children with a second toe of reasonable size compared with that of the opposite thumb, and for children whose parents may be satisfied with less than optimal function and/or appearance of the thumb (see Figs. 51-2 and 51-3). Great toe transfers tend to provide a broader and stronger surface area for pinch compared with second toe transfers.⁶⁶ Complete great toe transfers and trimmed toe transfers (see Fig. 51-4) are more commonly used in children with traumatic thumb amputations. Great toe wraparound techniques should not be performed in children, because they limit the potential for growth.

Alternative options to lengthen digits in cases of partial transverse arrest include web space deepening, nonvascularized toe phalangeal bone grafting, and distraction lengthening. Augmentation of hypoplastic digits with nonvascularized toe phalangeal bone grafts may be used as an

adjunctive procedure in children with adactyly to provide improved length and possibly some growth potential when harvested extraperiosteally and performed before 1 year of age⁷¹⁻⁷⁵ (Figs. 51-6 and 51-7). However, toe phalangeal bone grafts cannot provide the improved motion, sensibility, length, and function provided by a toe transfer. In our experience, growth after nonvascularized toe phalangeal bone grafts has been modest at best.

Bone lengthening in the hand is an application of the established technique of distraction osteogenesis.⁷⁶ Lengthening the metacarpals in cases of symbrachydactyly provides increased length and a greater lever arm and depth of grasp, but it does not provide motion.¹⁸ The length gained with distraction osteogenesis is superior to that achieved by phalangeal bone grafting, although it requires a prolonged period of treatment.^{73,74,76} Because of the lack of motion obtained with distraction lengthening, toe transfer remains the optimal treatment option.

Fig. 51-6 A and B, This 4-year-old girl had a transverse failure of formation of her left middle and ring fingers at the level of the proximal interphalangeal joints. C, She underwent nonvascularized toe phalangeal bone grafts from the proximal phalanges of the second and third toes. D and E, Subsequent lengthening of the middle and ring fingers. Radiographs show the stabilization of the toe phalangeal bone grafts to the proximal phalanges using longitudinal K-wires. F, Subsequent shortening of the second and third toes in the donor left foot.

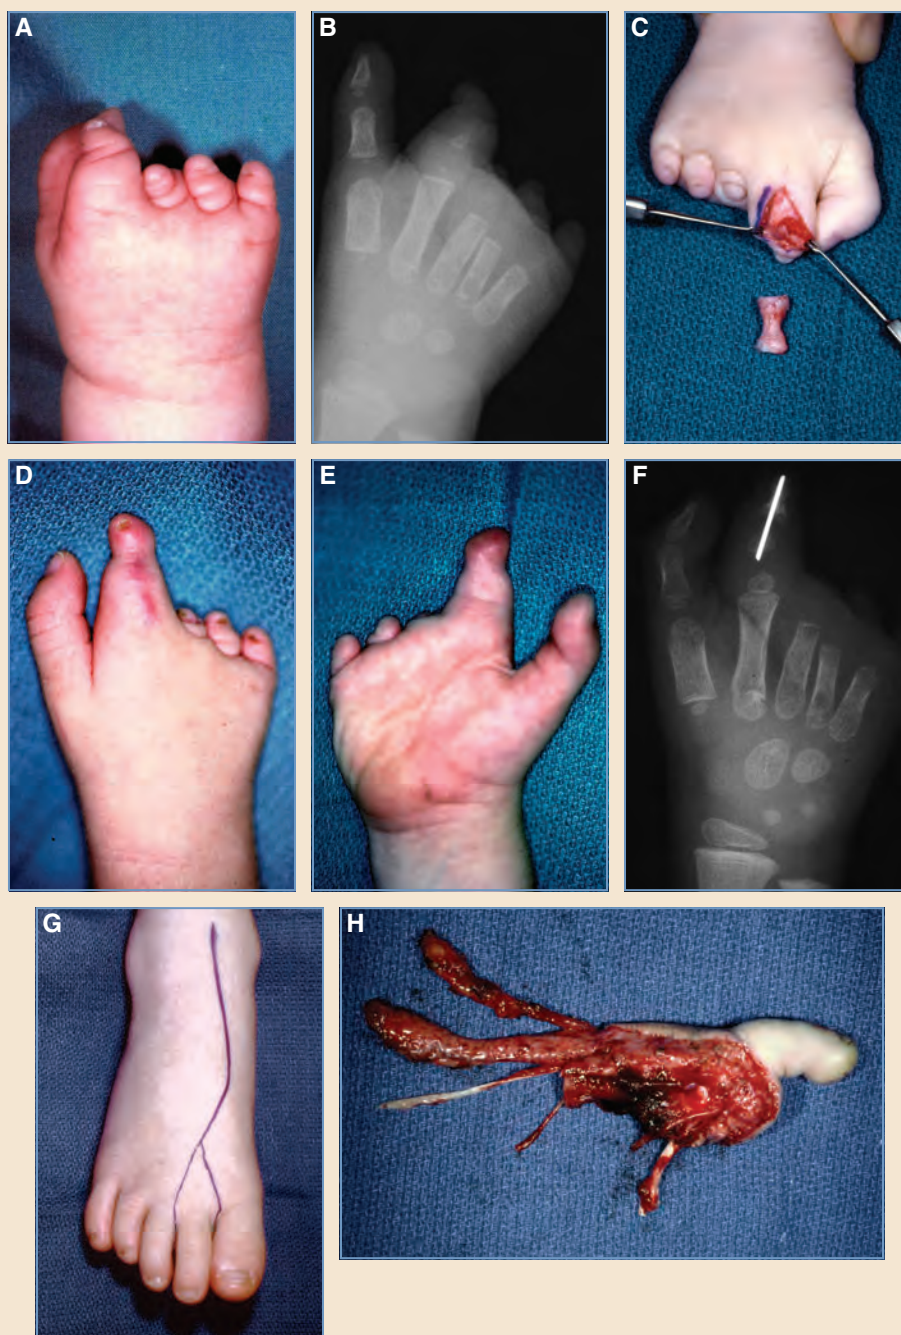

Fig. 51-7 A and B, A transverse failure of formation of the right hand with a remnant of the proximal phalanx of the index finger. C, The patient underwent nonvascularized toe phalangeal bone grafting of the right index finger at 6 months of age. D-F, Subsequent lengthening and stabilization of the right index finger 1 year postoperatively. G and H, At 2 years of age, he had a right second toe transfer into the middle finger position. (The blue marking indicates the surgical incisions.)

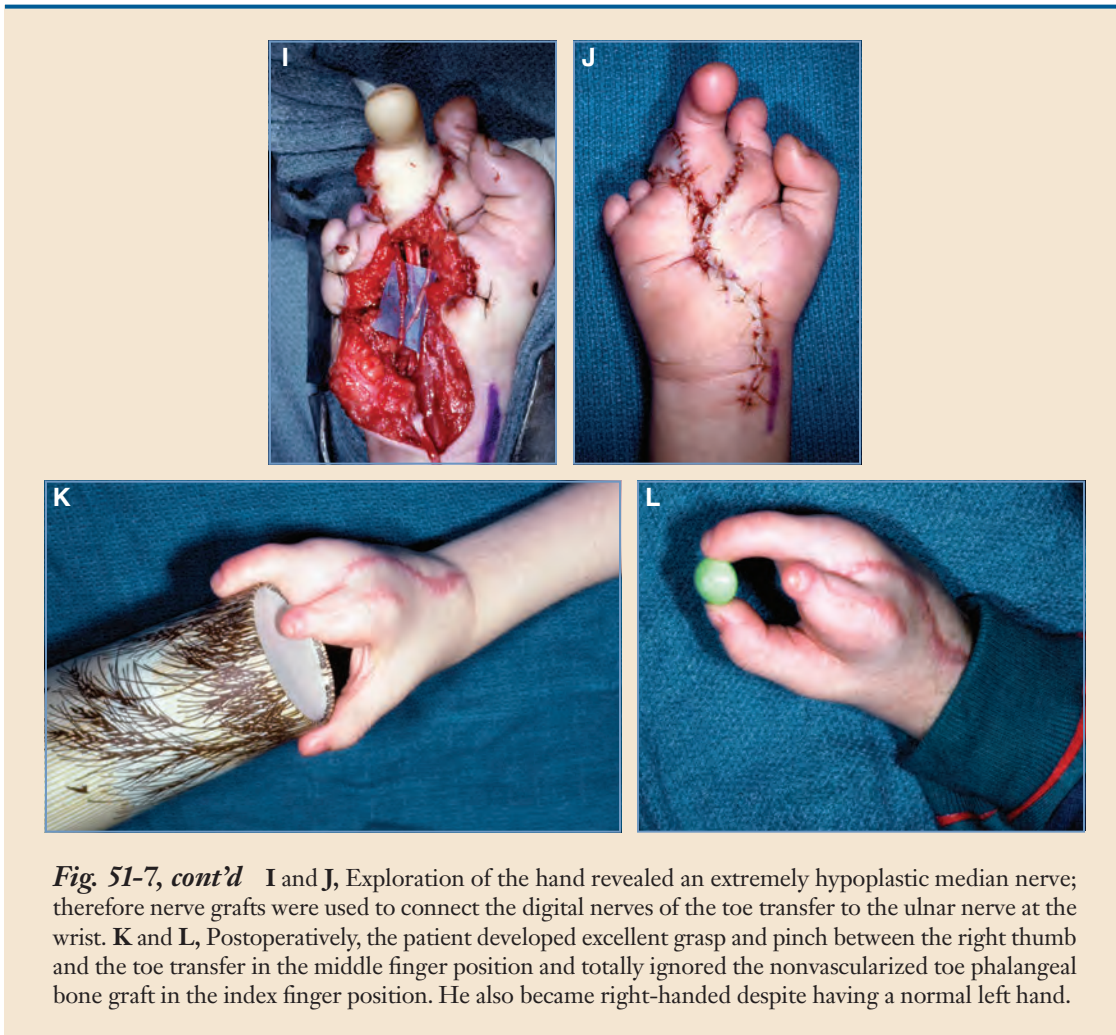

Fig. 51-7, cont'd I and J, Exploration of the hand revealed an extremely hypoplastic median nerve; therefore nerve grafts were used to connect the digital nerves of the toe transfer to the ulnar nerve at the wrist. K and L, Postoperatively, the patient developed excellent grasp and pinch between the right thumb and the toe transfer in the middle finger position and totally ignored the nonvascularized toe phalangeal bone graft in the index finger position. He also became right-handed despite having a normal left hand.

Contraindications

The most obvious contraindication to toe transfer is the absence or significant deformity of the toes. In general, however, even in children with severe cleft foot deformity, at least one of the two toes can be transferred without affecting the child's gait. Other contraindications include an inexperienced surgical team and/or surgical unit, absent recipient nerves, a transverse deficiency proximal to the distal carpus, and psychosocial factors in the parent or child.⁷

The family should be informed of and prepared psychologically for the significant amount of time and energy that will be required during the preoperative and postoperative period. The family must understand and accept that a toe transfer can fail. If this occurs, their child will have the same deficit in the hand and a new deformity in the foot. If the parents and/or the child cannot accept the time commitment and the potential risk of failure, this surgery should not be considered.

Toe transfer surgery is never urgent, and parents should be reassured that the operation can be performed when they are comfortable with it. Waiting until the child is 2 to 3 years of age or even older is perfectly reasonable, because the ability for central motor and sensory reintegration of the new digits is still possible.

PREOPERATIVE PLANNING

A child with one normal hand and a contralateral adactylous hand or a contralateral hand with a single digit or isolated thumb should be considered for a toe transfer (Figs. 51-8 through 51-11; see Box 51-1 and Fig. 59-7). Even in symbrachydactyly, in which some of the proximal anatomy may be anomalous or absent, a toe transfer can provide improved function. Toe transfers for unilateral adactyly should be positioned to allow the widest grip possible, because the opposite, normal hand will probably be used for all fine manipulation.

Fig. 51-8 A-C, This 3-year-old girl had a severe radial longitudinal deficiency affecting the left thumb, index finger, and middle finger. D, Dissection of the hand revealed normal extensor tendons and flexor tendons extending to the remnant of the base of the proximal phalanx of the thumb. E, Dissection of the right second toe transfer showing the extensor digitorum communis tendon and branches of the superficial and deep peroneal nerves. F and G, The postoperative result. A portion of the right second toe metatarsal was used to elongate the proximal phalanx of the left middle finger.

Fig. 51-9 A and B, This 6-month-old girl had a transverse failure of formation of all four fingers and an unstable thumb at the metacarpophalangeal joint. C, The parents refused a toe transfer. At 6 months of age the patient underwent an attempt at creating a post on the ulnar border of the hand using a nonvascularized toe phalangeal bone graft. D and E, The result of the nonvascularized toe phalangeal bone graft is shown, with minimal lengthening of the ulnar border of the hand. F and G, She subsequently underwent a left second toe transfer into the small finger position at 2 years of age. At 2 years and 7 years postoperatively, she had very precise pinch. H and I, At 2 years and 7 years postoperatively, she had strong grasp between the thumb and the toe transfer in the small finger position. The patient and her parents refused to allow the nubbins to be excised. J, The appearance of the left foot 7 years postoperatively.

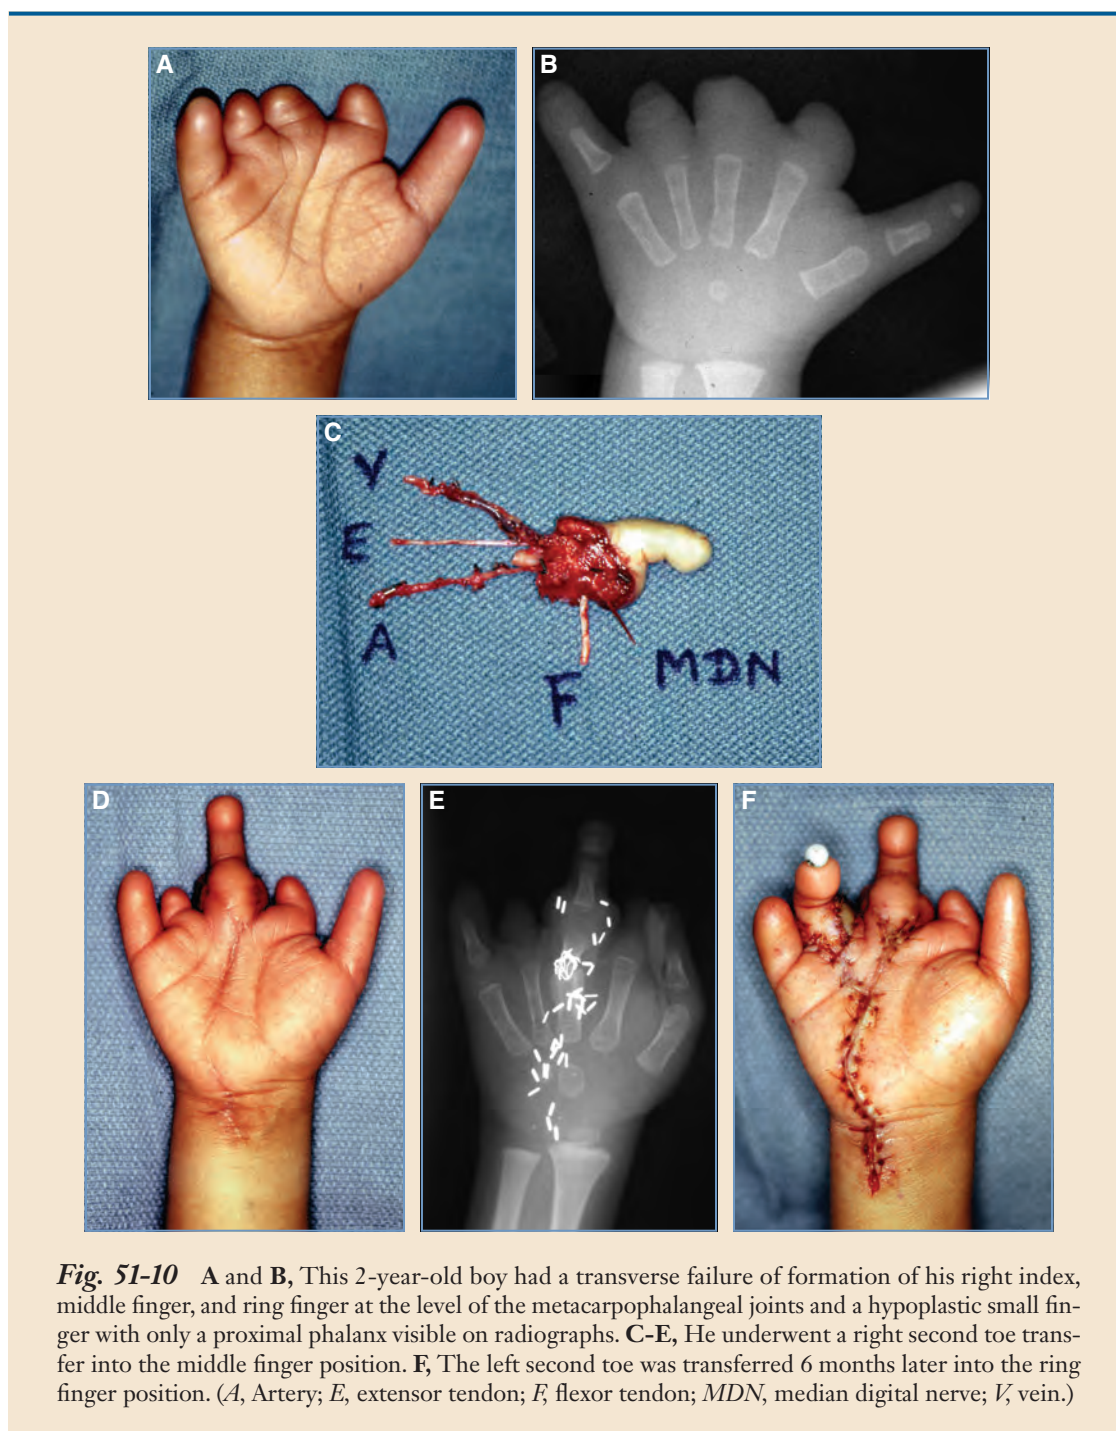

Fig. 51-10 A and B, This 2-year-old boy had a transverse failure of formation of his right index, middle finger, and ring finger at the level of the metacarpophalangeal joints and a hypoplastic small finger with only a proximal phalanx visible on radiographs. C-E, He underwent a right second toe transfer into the middle finger position. F, The left second toe was transferred 6 months later into the ring finger position. (A, Artery; E, extensor tendon; F, flexor tendon; MDN, median digital nerve; V, vein.)

Fig. 51-10, cont'd G and H, The hand is shown 3 years postoperatively. I-K, Pinch function and grasp function and the appearance of both feet 3 years postoperatively.

Fig. 51-11 A and B, This 1-year-old boy had a transverse failure of formation of his left index, middle, ring, and small fingers at the level of the distal metacarpals, but his thumb was present. C-E, At 2 years of age, he underwent simultaneous bilateral second toe transfers into the middle and small finger positions of his left hand. F, The immediate postoperative result. G-I, The appearance of his left hand 3 years postoperatively. He is able to pick up small objects and use his left hand as an assist hand for grasping and lifting. (A, Artery; DN, digital nerve; E, extensor tendon; F, flexor tendon; N, dorsal nerve; V, vein.)

In children with bilateral deficiencies, the dominant hand should be reconstructed to allow opposition for fine motor control, whereas the opposite hand should have wider positioning for grasp.³ For a dominant hand, one toe should be placed in the thumb position to create a radial post and another toe placed in the middle or ring position to facilitate fine pinch. For a non-dominant hand, one toe is placed in the thumb position, and the other toe is placed in the ring or small finger position to provide wide grasp.

The primary requirements of a reconstructed thumb include stability, sensibility, the ability to oppose, and sufficient flexion and extension for grasping.^{20,66,77} Positioning a toe transfer depends on the presence of a competent thumb carpometacarpal joint. If this joint is absent, the transferred toes will have to be positioned so that they face each other, because most of the motion will occur at the interphalangeal joints. When transferring a great toe for thumb reconstruction, surgeons should consider the relative valgus angulation of the first metatarsophalangeal joint. Typically the first MTP joint has 10 degrees of valgus angulation; therefore transfer of the ipsilateral great toe to the thumb results in optimal positioning, with the new thumb pointing ulnarly.

Positioning and Marking

The child is placed in a supine position on the operating table, and all prominences are well padded. General anesthesia is given in all cases. Although an axillary block used in conjunction with general anesthesia has been shown to increase peripheral circulation to the hand, the technique is rarely applied in children.³⁵ Some surgeons have advocated axillary blocks to diminish the need for intraoperative and postoperative analgesia, whereas others have recommended continuous brachial plexus infusion postoperatively.^{8,20} Because of the length of the surgery, a Foley catheter is always placed to monitor the child's urine output and overall fluid status. Each patient is hydrated with standard intravenous fluids, but a central venous catheter is not used routinely.

Preoperatively, a handheld Doppler ultrasound probe is used to mark the location of the dorsalis pedis artery and/or the posterior tibial artery, depending on the local anatomy and the needs of the recipient hand.^{19,78} The dorsalis pedis artery is traced distally into the first dorsal metatarsal artery (FDMA), which lies between the great toe and second toe metatarsals. The location of the dorsal veins may be marked after a tourniquet is placed around the calf and before the start of the case, or after the patient is draped and the thigh tourniquet is inflated to 100 mm Hg (see Fig. 51-5, C). A tourniquet is applied around the upper arm. Because of the need for a split-thickness or full-thickness skin graft in most cases, a sterile thigh tourniquet is used to allow later access to the groin or thigh.

SURGICAL TECHNIQUE

If two teams are available, the hand and foot can be dissected simultaneously. Before beginning the operation, the teams convene to review the anatomy, the radiographs, and the needs of the particular child. If only one team is available, the hand usually is dissected first to confirm that the specific tendons and digital nerves are available for subsequent tendon and nerve repairs.

Dissection of the Foot

Dissection of the foot is performed under tourniquet control after exsanguination with an Esmarch bandage. Either 2.5× or 3.5× loupe magnification is sufficient for dissecting the structures in a child's foot. A racquet-shaped or V-shaped incision is marked on the foot, surrounding either the great or second toe (see Figs. 51-5, C, and 51-7, G). The dorsal skin incision begins proximally at the level of the cuneiform joints and extends distally in a longitudinal fashion over the dorsal

aspect of the first and second intermetatarsal space. This allows dissection of the dorsal veins and identification of the dorsalis pedis artery. The V-shaped dorsal skin flap extends either around the tibial aspect of the great toe and first web space or around the first and second web spaces, depending on whether the great toe or second toe is harvested. The two incisions usually create a plantar triangular flap with its apex at the MTP joint.

Dissection is continued through the dorsal subcutaneous tissues, with careful cautery of small draining veins. Usually, one dominant dorsal vein can be identified and dissected distally to the level of the dorsal V-shaped flap and proximally as far as the level of the ankle joint, if needed. The dorsalis pedis artery and deep peroneal nerve are identified proximally by dividing the extensor hallucis brevis tendon and dissecting from proximal to distal to identify the FDMA.⁷⁹ Alternatively, dissection of the FDMA can be started distally in the first web space, tracing the FDMA from distal to proximal into the dorsalis pedis artery, while an assistant retracts the great and second toes apart.^{7,12,80} Depending on which system appears more dominant, the dorsal or plantar arterial system is chosen for transfer.⁸ The dorsalis pedis artery typically divides into two branches at the level of the tarsometatarsal joint. The FDMA continues distally between the first and second metatarsals in one of three patterns, and the second communicating branch passes deep to anastomose with the plantar arch and continues distally as the first plantar metatarsal artery (FPMA).

The location and size of the FDMA can be quite variable.⁵⁷ It may lie in a dorsal, intramuscular, or plantar position. If the FDMA cannot be identified, the FPMA may be used for anastomosis and extended by a vein graft.³ If both the dorsalis pedis and the first dorsal metatarsal arteries are absent or hypoplastic, the great toe may still be transferred using the medial plantar arterial system.⁸¹ In most cases we use only one artery and one vein as the vascular pedicle.

In children with a congenital cleft foot, the great toe is usually transferred on the posterior tibial artery pedicle. The dissection begins proximally, just posterior to the medial malleolus, where the artery lies between the flexor digitorum longus and the flexor hallucis longus tendons, accompanied by the tibial nerve and posterior tibial vein. The artery can be traced distally to the medial plantar arterial system supplying the great toe.

The flexor hallucis longus tendon to the great toe or the flexor digitorum longus and flexor digitorum brevis tendons to the second toe can be identified by dissection through the plantar fascia and flexor tendon sheath at the level of the MTP joint. On either side of the tendon, the medial and lateral plantar digital nerves are identified and traced back to the level of the common digital nerves. Extra length may be gained by splitting the bifurcation of the nerve more proximally before transecting each digital nerve. The digital nerves are tagged with small microvascular clips to make their identification easier when it is time to repair them to the digital nerves in the hand.

The proper plantar digital arteries lie dorsal to the digital nerves and can be traced proximally to the FPMA. This vessel can be preserved and used as a secondary recipient artery if needed. All branches from the FDMA and/or FPMA supplying the second toe should be cauterized or clipped if the great toe is transferred. Alternatively, all branches from the FDMA or FPMA supplying the great toe should be cauterized or clipped if the second toe is transferred. The dissection is continued in the first web space, identifying the deep peroneal nerve, which must be carefully divided into separate fascicles supplying the adjacent great toe and second toes. The fascicles serving the toe to be transferred are then divided from the main trunk of the deep peroneal nerve for later repair to the superficial branch of the radial nerve in the hand.

The extensor hallucis longus is dissected proximally and divided when the great toe is transferred. Alternatively, the extensor digitorum communis and extensor digitorum brevis tendons are dissected and divided proximally when the second toe is transferred (see Fig. 51-8, *E*). Both the

flexor and extensor tendons should be divided as long as possible to allow repair away from the site of osteosynthesis and to provide enough length in cases in which the proximal motor units are short or deficient. The flexor hallucis longus to the great toe or the flexor digitorum longus to the second toe may be difficult to harvest without creating a long incision on the plantar surface of the foot. To gain more length, the tendon may be divided through a dorsal approach after the metatarsal osteotomy.

When the thumb is reconstructed using a second toe, the osteotomy may be performed either at the MTP joint or more proximally in the metatarsal shaft. The great toe may be harvested at the level of the MTP joint or through the base of the proximal phalanx; but a more proximal osteotomy through the great toe metatarsal may interfere with gait. If the MTP joint is chosen, the osteotomy is performed at an oblique angle so that the joint is fixed in hyperextension to prevent further hyperextension of the toe when it is placed in the thumb position.

After the osteotomy has been performed, further dissection of the arterial and venous pedicles to increase their length can be completed. All small branches are carefully clamped with small microvascular clips or cauterized with bipolar electrocautery. Once the dissection is complete, the tourniquet is deflated to allow reperfusion of the toe, which may take up to 15 minutes. The vascular pedicle can be irrigated with dilute (1:20) papaverine solution, and laparotomy pads soaked in warm irrigation fluid may be placed over the foot to improve digital blood flow.

Dissection of the Hand

If two teams are available, dissection of the hand and the foot may be performed simultaneously. In symbrachydactyly a horizontal incision may be made across the residual nubbins to expose tiny vessels that can be traced proximally.¹⁹ The vascular, nerve, and tendon anatomy is usually anomalous in symbrachydactyly; in these cases, the hand is dissected before the foot to ensure that adequate nerves and tendons are present in the hand.⁴⁹ In congenital constriction ring syndrome, normal anatomy is usually preserved out to the level of the amputation³ (see Fig. 51-8, D).

The dorsum of the hand is incised to expose the extensor tendons and, if available, the superficial branch of the radial nerve. The incision is usually designed longitudinally so that the V-shaped dorsal skin flap from the toe will interdigitate after transfer of the digit. A dorsal vein, preferably a branch of the cephalic or basilic vein, is identified and tagged for the later venous anastomosis.

The volar surface of the hand is opened in a zigzag fashion across the wrist crease. The median and/or ulnar nerve are carefully dissected to assess potential sites for coaptation of the plantar digital nerves. Through this same incision, the flexor tendons are dissected and assessed for their excursion. The transverse carpal ligament should be left intact. Once adequate tendons, nerves, and vessels have been identified in the hand, the wounds are provisionally closed with staples to prevent excessive swelling. The tourniquet on the upper extremity is deflated, and the vascular pedicle to the toe transfer is subsequently divided. The arterial pedicle is usually ligated with 3-0 silk and reinforced with small microvascular clips.

Closure of the Foot

The defect in the foot can be closed primarily; rarely is a split-thickness skin graft required. The defect left after a second toe transfer is closed by first closing the gap between the first and third metatarsals. The intermetatarsal ligaments arising from the adjacent metatarsals are sutured together using a heavy Ethibond suture, closing the gap created by harvesting the toe. Meticulous hemostasis is obtained with Bovie electrocautery. If drainage is persistent, a small Jackson-Pratt drain can be left in the wound after closure. The skin is closed with interrupted 4-0 chromic catgut horizontal mattress sutures.

The defect created by harvesting a great toe is similarly closed primarily. Reconstruction of an intermetatarsal ligament is not required.

Transfer of the Toe

After a toe is harvested, the recipient site in the hand is prepared for osteosynthesis. The tourniquet is reinflated to 250 mm Hg to ensure a bloodless field. If a segment of metatarsal has been harvested, the periosteum is elevated from its base, and the periosteum is elevated from the distal aspect of the recipient metacarpal bone in the hand. Rotation of the toe transfer is determined by placing the base of the metatarsal at the osteosynthesis site and checking the relationship of the toe to the remaining digits or to the proposed location of a future toe transfer. In general, a toe-to-thumb transfer is placed in 120 degrees of pronation but should be adjusted as needed to allow adequate grasp and/or pinch, depending on the needs of the child. The exact rotation of the toe is marked on the corresponding surfaces of the metatarsal and metacarpal at the osteosynthesis site to allow fixation in the correct position. Any excess length of metatarsal can be removed using an oscillating saw.

Excellent fixation can be obtained with the use of 90-90 intraosseous wiring between the base of the metatarsal and the recipient bone in the hand. With the use of a 0.035-inch K-wire, two holes are drilled perpendicular to each other, approximately 5 mm from the base of the metatarsal and parallel to the cut surface of the bone. Similarly, two matching holes are drilled through the metacarpal. The surgeon passes two 26-gauge stainless steel wires through the holes and twists them clockwise while pulling perpendicular to the osteosynthesis site. Alternating back and forth between the two wire loops allows the bone ends to be opposed accurately (see Figs. 51-4, *E* and 51-10, *E*). The surfaces of the stainless steel wires change from a glistening, shiny appearance to a dull gray when the wire has reached its maximal tension. K-wires may be required for added stability but are not usually necessary. Some surgeons use K-wires exclusively, arguing that they do less damage to the growth plate, are quicker to apply, and are stable enough alone to achieve union.⁷

If the toe has been harvested through the MTP joint, the base of the toe proximal phalanx creates a new joint with the head of a metacarpal, but stability and mobility may be difficult to achieve because of the limitations of collateral ligament repair. The strong volar plate can be repaired to the volar aspect of the metacarpal using a heavy suture or mini-suture anchors.

In situations in which a suitable foundation for a thumb is absent, the adjacent index finger metacarpal may be pollicized. This allows osteosynthesis of the base of the toe transfer to the pollicized index metacarpal base. Alternatively, a second toe, with a long metatarsal, may be stabilized with K-wires or interosseous wires to the radius (Vilkki procedure) or with a residual carpal bone to create a pseudarthrosis.⁵⁰

Once bony stability has been achieved, the extensor tendon is reconstructed. The extensor hallucis longus to the great toe or the extensor digitorum communis to the second toe is repaired to an available extensor tendon in the hand. The repair is performed under tension with overlap of the tendons. Multiple horizontal mattress sutures using 4-0 nylon are sufficient to allow early motion. When reconstructing a new thumb, the extensor indicis proprius or an adjacent extensor tendon (extensor digitorum communis) to the index finger remnant is usually transferred as a donor tendon. When a finger is reconstructed, a quadrigia effect caused by tethering of the extensor digitorum communis with a common muscle belly to the absent digits must be prevented by releasing adjacent extensor tendons.

Only one flexor tendon, usually the flexor hallucis longus to the great toe or the flexor digitorum profundus to the second toe, is repaired to a recipient flexor tendon in the hand, especially

in children with symbrachydactyly or a transverse deficiency. If a flexor tendon with adequate excursion cannot be identified, a primary tendon transfer may be required. The flexor tendon repair is performed by overlapping or weaving the tendons using multiple 4-0 nylon horizontal mattress sutures. To prevent a quadrigia effect, adjacent flexor tendons that may tether the newly reconstructed flexor tendon to the toe are divided.

Neurorrhaphy of the medial and lateral digital nerves and the deep peroneal nerve of the toe transfer to the recipient nerves in the hand is then performed under a microscope. The site of neurorrhaphy is determined by the quality of recipient nerves in the hand and the length of the nerve harvested from the foot. If possible, nerves are repaired more proximally to ensure the best recipient nerve is selected. The medial and lateral digital nerves are repaired in an end-to-end epineurial fashion to residual stumps of the proper or common digital nerves using 10-0 nylon in an interrupted suture technique. The deep peroneal nerve is repaired to a branch of the superficial radial nerve. If recipient digital nerves are inadequate or unavailable, the toe digital nerves can be coapted in an end-to-side fashion to the median or ulnar nerves, or, alternatively, nerve grafts from the superficial or deep peroneal nerves can be interposed (see Fig. 51-7, *I*).

Vascular anastomoses should be performed after the tourniquet has been deflated to allow reperfusion of the upper extremity and then reinflated after 20 minutes. Before reinflation of the tourniquet, a microvascular clamp can be applied to the recipient artery (radial or ulnar artery) to be sure the other digits remain perfused. If the hand remains pink, the arterial anastomosis can be performed in an end-to-end fashion.

The venous anastomosis is usually performed before the arterial anastomosis. It is preferable to harvest as long a vein as possible and anastomose it end to end to a large, more proximal vein, typically the cephalic or basilic vein at the wrist. The anastomosis is performed using standard microsurgical techniques under a microscope with 10-0 nylon sutures. After the vein has been anastomosed, the recipient vein is occluded proximally with a small microvascular clamp.

The site of the arterial anastomosis depends on which toe arterial system (dorsal or plantar) was harvested and the location of the recipient radial or ulnar artery. End-to-side or end-to-end anastomosis to the ulnar artery or the dorsal branch of the radial artery in the anatomic snuffbox can be performed if a long arterial pedicle is available, usually the dorsalis pedis–FDMA or the posterior tibial artery. If the FPMA system was harvested, it is usually too short to reach the radial artery. Occasionally, it can be anastomosed to the superficial palmar arch or to a common digital artery, but it is usually better to elongate the FPMA with an interposition vein graft anastomosed on a back table before performing bony osteosynthesis and tendon and nerve repairs. The arterial anastomosis is performed similar to that of the vein, using 10-0 interrupted nylon sutures.

The tourniquet is deflated, leaving the single microvascular clamp on the proximal side of the venous anastomosis in place. This creates a high-pressure column of blood running through the toe, theoretically expanding collapsed vessels, which may be in spasm. The vascular anastomoses are bathed in dilute (1:20) papaverine solution, and the hand is warmed with laparotomy pads soaked in warm irrigation fluid. The patency of the anastomoses is checked by the milking test, and the vascular clamp is removed from the proximal side of the venous anastomosis.

The incisions are loosely closed with interrupted 4-0 and 5-0 chromic catgut mattress sutures. If the closure is under too much tension, a split-thickness skin graft should be applied. A 14/1000-inch split-thickness graft from the thigh is preferable. The skin graft is not meshed, but small fenestrations are made with a No. 11 blade scalpel to allow drainage. Alternatively, a full-thickness skin graft from the groin is used. The skin graft can be excised at a later date to improve appearance. A sterile pulse oximeter probe is applied to the toe transfer before the dressings are applied and is left in place for postoperative monitoring.¹⁶ A loose sugar-tong splint is applied to the upper extremity, and the foot is immobilized in a posterior plaster splint.

POSTOPERATIVE CARE

The child is monitored in a pediatric intensive care unit for 1 to 2 days postoperatively and then transferred to the general pediatric floor for another 5 to 7 days. The hand and foot are elevated, and the hand is kept warm with a heating blanket. The core body temperature, heart rate, blood pressure, respiratory rate, systemic oxygen saturation and urine output are monitored closely. The toe transfer is monitored hourly for color, capillary refill, oxygen saturation, and pulse rate. Differential pulse oximetry is superior to temperature monitoring and is a simple, continuous way to noninvasively monitor toe-to-hand transfers in children.³⁶ The toe transfer pulse rate corresponds with patency of the arterial anastomosis, and any decrease or loss of the pulse rate compared with the systemic heart rate may indicate that the arterial anastomosis is compromised. The oxygen saturation corresponds to the patency of the venous anastomosis, and any decrease in the oxygen saturation for an extended period of time, compared with the systemic oxygen saturation, may indicate thrombosis of the venous anastomosis. If the appearance of the toe transfer or the differential pulse oximetry indicates compromised perfusion to the toe transfer, the patient should be immediately returned to the operating room for exploration and possible revision of the microsurgical anastomoses.

The child is kept sedated with the use of opiates and benzodiazepines, as needed. Anticoagulation with dextran 40 (0.36 ml/kg/hr) is continued for 5 days. An 81 mg aspirin tablet is started on postoperative day 1 and continued daily for 4 weeks. The dextran infusion rate is reduced to half on postoperative day 6 and then discontinued on day 7. A first-generation cephalosporin is given intravenously for 48 hours postoperatively. Intravenous fluids are maintained based on weight until the child is tolerating an oral diet. The hand and foot dressings are changed on postoperative day 5 to 7. If there is any concern with the perfusion to the toe transfer, the cast and dressings should be released or removed completely, because occasionally the plaster splint and dried blood can combine to form a constrictive cast, producing external pressure on the anastomoses. Ambulation on the donor foot can begin as soon as the child is comfortable doing so.

The plaster hand and foot splints are removed at the first postoperative visit at 2 weeks, and the toe transfer is inspected for capillary refill and skin graft take. The foot incision is checked; occasionally, some patients require local wound care for minor dehiscence or oral antibiotics for localized cellulitis. A removable Thermoplast splint is fabricated to protect the toe transfer, and the parents and child are instructed on passive and active range-of-motion exercises. A hand therapist may assist with the therapy if the family is apprehensive. K-wires are removed if necessary at 6 weeks. The parents may relate that their child is having dysesthesias as reinnervation occurs. They should be instructed that these sensations are normal and will resolve as the nerves regenerate.⁷

TREATMENT OUTCOMES AND COMPLICATIONS

Toe-to-hand transfers have helped restore function in children with congenital differences of the hand, including longitudinal deficiency, transverse deficiency, symbrachydactyly, congenital constriction ring syndrome, and after severe trauma.

O'Brien et al²² reported the first microsurgical toe-to-hand transfer in a child in 1978. The great toe was successfully transferred to treat two children with thumb hypoplasia. In both children the toe transfer was being used for "many tasks" 1 year postoperatively, and no problems with gait were noted in either child. Nyarady et al⁴⁰ performed a second toe transfer for thumb hypoplasia in a 13-year-old boy in 1983. The patient developed 6 mm of two-point discrimination by 4 months after the operation and had satisfactory flexion and extension of the thumb. Although index finger pollicization remains the benchmark treatment for thumb hypoplasia and aplasia, these early reports fueled interest in treating children with more severe congenital hand differences with toe transfers.

Yoshimura⁸² reported the first large series of pediatric toe transfers in 1980. He successfully performed 33 toe transfers in 28 patients, 12 of whom were children. All but two cases were performed for traumatic amputations; one child had a congenital deficiency of the thumb, the index finger, and the middle finger, and another child had an intrauterine amputation of one finger. In all the pediatric cases, the epiphyseal plate was undisturbed, and growth potential was theoretically maintained. But based on a follow-up study 4 years after the initial paper, the growth of the transferred toes was found to be less than that of the contralateral toes.⁸³

In contrast, Chang and Jones²⁶ documented excellent potential for digital growth after toe transfer. A comprehensive radiographic study of toe transfers performed in children 2.8 to 13 years of age demonstrated that the epiphyseal plates remained open in 27 of 28 phalanges at a mean of 12 months' follow-up (range 1 to 36 months). In four patients in whom radiographic comparison was possible, the amount of linear growth of the toe transfer was equal to the growth of the contralateral, nontransferred toe. Wei and Mardini¹² found that the trimmed toe transfer does not affect growth, and they regularly use this technique in children with traumatic amputations. Kay and Wiberg⁸ found that the length of the toe transfer varied from 70% to 104% of the length of the contralateral toe.

May et al⁷⁷ reported on a case of bilateral toe-to-thumb transfers in a 9-year-old boy with aplasia of the thumb and the index and middle fingers of both hands. In each procedure the great toe was harvested because of a cleft foot anomaly. Eighteen months postoperatively the child required bilateral thumb interphalangeal joint arthrodeses for instability and an abductor digiti minimi transfer for improved thumb opposition. The patient had no gait abnormalities at the final follow-up and was using the thumbs regularly for many activities but continued to use the ring and small fingers for lateral pinch of small objects. Two-point discrimination was 9 to 10 mm at the 3-year follow-up visit.

Gilbert¹⁵ reported on 21 second toe transfers performed between 1977 and 1980 in 17 children with congenital hand differences. Four thumbs and 17 fingers were reconstructed in children ranging in age from 18 months to 13 years (12 transfers were performed in children younger than 3 years of age). One venous thrombosis occurred, which was detected 4 hours postoperatively and treated by immediate reoperation. The child was given 50 mg of aspirin daily for 10 days, and the toe transfer remained viable. Gilbert found that the results were better in children with congenital constriction ring syndrome, compared with results in children with congenital aplasia, because the structures were more "normal" proximally. Restoration of motion was minimal, with a mean active combined flexion of the proximal and distal interphalangeal joints of 40 degrees (range 0 to 80 degrees). Five secondary tenolysis procedures provided negligible improvement. Sensibility was assessed subjectively, and most children were unable to discriminate any difference between the transferred toe and the normal digits. Growth of the toe transfer was similar to that of the contralateral, nontransferred second toe. No deficits in gait were noted, but the dorsal donor site scar was sometimes hypertrophic.

Lister¹⁷ reported on his experience with 12 children 10 months to 8 years of age in whom the second toe was used to reconstruct the thumb in congenital constriction ring syndrome, symbrachydactyly, and true transverse arrest. Active motion was achieved in only 3 of the 11 children, and 1 child underwent an unsuccessful tenolysis 2 years postoperatively. Two-point discrimination was not assessed, but all children demonstrated "sweating and good tactile adhesion" by 6 months postoperatively.

Shvedovchenko²³ reported on 103 successful toe transfers in 66 children 3 to 14 years of age with congenital and posttraumatic deformities of the hand. The second toe, the small toe, and a composite of the second and third toes were used to reconstruct the hands of children with brachydactyly, ectrodactyly, adactyly, and traumatic loss. Functional outcomes and complications were not reported.

Vilkki¹⁹ reported his results of 18 toe transfers in children for congenital adactyly. One failure occurred, resulting from anesthesia complications. Five reexplorations for immediate postoperative vascular problems were required in the other 17 children. Pinch was restored in 14 of 17 hands. Linear growth of the transferred toes occurred without problems in the phalangeal epiphyses; however, the metatarsal head epiphyses showed evidence of growth arrest in two children.

Kay⁷ successfully transferred 125 toes in children without a single loss. In 1996 he published his initial series of 40 children (9 months to 14 years of age) with 66 toe transfers.^{8,9} A single toe was transferred in 14 children, and two toes were transferred in 26 children to reconstruct hands with congenital malformations, traumatic loss, or infection. Five children required early postoperative vascular reexploration, but infection occurred in only one case. At a mean of 45 months postoperatively, the children and their parents were reviewed for functional and psychological performance. Similar to earlier reports, the range of motion achieved was less than expected, with an average of 60 degrees total active range of motion. Tenolysis was performed in 15 children, and tendon transfers were required in 7. A secondary rotational osteotomy was performed in 4 children, and digits were augmented with nonvascularized phalangeal bone grafts in 3. In children in whom two-point discrimination was thought to be reliable, the mean was 5 mm, and all children developed protective sensibility.

Bellew and colleagues^{63,64} performed a detailed psychological evaluation of a subset of Kay's series 1 year and 10 years after transfer. One year postoperatively, 92% of parents thought the reconstruction improved their child's hand function, and 83% thought it improved the overall appearance of the hand. Ten years after transfer, 90% of parents and 88% of patients were satisfied with the outcome of the surgery. With regard to function, 90% of parents and 94% of patients stated the surgery had improved hand function. Patients who had grown into adulthood had scores within the normal range on depression and anxiety measures and a higher than average self-esteem.

Toe transfers have also been used for reconstructing congenital digital loss in older children. Spokevicius and Razdevicius¹⁴ successfully transferred four toes in three children 11 to 17 years of age with congenital malformations. The preoperative indication was improved appearance in all three children. One 17-year-old girl required reexploration and revision of the arterial anastomosis in the early postoperative period, and a 12-year-old girl developed arterial insufficiency on the first postoperative day, requiring heparinization and a brachial plexus block to restore flow. Two-point discrimination was documented in three of the four toe transfers, and grip strength and dexterity improved in all cases.

Wei and colleagues^{12,51} performed 45 complete toe or partial toe transfers in 28 children and adolescents (range 2 to 16 years of age) for traumatic defects. Three patients required postoperative reexploration. One toe transfer failed completely, and partial pulp loss occurred in two digits. Static two-point discrimination averaged 5 mm, and the range of motion averaged 69 degrees at the metacarpophalangeal joint, 38 degrees at the proximal interphalangeal joint, and 13 degrees at the distal interphalangeal joint of the second toe transfers. The average motion at the interphalangeal joint of the transferred great toes was 15 degrees.

Van Holder et al³⁸ reconstructed the hands of 14 children with congenital constriction ring syndrome, symbrachydactyly, and transverse failure of formation using staged, double second toe transfers. Postoperatively, all of the toes had sensibility and mobility and provided improved function and appearance; however, all patients required at least one secondary procedure.

I (N.F.J.) have performed more than 100 pediatric toe-to-hand transfers. In a published series of 82 transfers in 68 children with congenital hand differences, the overall success rate was 97.6%.⁴⁶ Seven toes (8.5% of transfers) required reexploration for salvage, and all children regained light touch perception and improved hand function. Jones and Kaplan⁴⁸ evaluated

15 children using a validated patient reported outcomes measure for the pediatric orthopedic patient population. They found that for most functional dimensions, children who underwent toe-to-hand transfer did not differ significantly from the “normal” pediatric population. Adolescent patients and their parents reported lower upper extremity function and sports/physical function scores relative to “normal” children. However, the same adolescent patients reported a higher overall happiness, compared with the general population.

CONCLUSION

Toe-to-hand transfer in children has become an accepted tool in the armamentarium of pediatric hand surgeons, although it remains a technically challenging undertaking, requiring a high level of skill on the part of the surgeon and the trust and patience of the child and parents. Miraculous improvement in function can be achieved in children affected by severe congenital hand differences such as symbrachydactyly, congenital constriction ring syndrome, and longitudinal deficiencies, and after traumatic amputations.

The appropriate age for toe transfer is 2 to 3 years of age, although the procedure can be successful in older children. Preoperative counseling providing the parents with the opportunity to meet and/or speak with other children and/or families who have undergone a toe transfer is very helpful. The child should be examined by a pediatrician for medical clearance and to rule out other associated anomalies before surgery. The appropriate toe to be transferred and the position to place the transfer on the hand are details that are specific to each child and should be discussed in detail with the child and parents before the operation. Informing the parents of the potential for the procedure to fail, with subsequent loss of the toe transfer, is essential.

A toe transfer involves many critical steps, but identification of the vascular pedicle and dissection of the toe are the most challenging. Positioning of the toe, osteosynthesis, and tendon repair are important steps that can be perfected with patience and experience.

Typically, only one artery and one vein are needed to provide adequate perfusion of the toe transfer. Closure of the incisions should be tension free, and split-thickness skin grafts may be necessary.

Postoperative care is critical to the success of a toe transfer. An initial stay in an ICU setting with sedation and transfer to a general pediatric floor after 2 to 3 days allows the most intensive monitoring during this critical period. Continuous differential pulse oximetry monitoring, intravenous dextran anticoagulation for at least 5 days, intravenous antibiotics, intravenous hydration, and a dressing change before discharge home help to ensure the success of a toe transfer.

The parents should be informed that sensation may take 3 to 6 months to return, and that motion of the transferred toe may improve over a 1- to 2-year period. These children may require a tenolysis, tendon transfers, bone grafting, an arthrodesis, an osteotomy, or scar revision to achieve their optimal functional and aesthetic outcome.

Although toe-to-hand transfer may not provide the most aesthetically pleasing result, and the motion achieved may seem less than ideal, the changes that occur in the lives of children after toe transfer are truly phenomenal. A 5-year-old child who is able to write his or her name for the first time, or an 8-year-old who can participate in sports such as baseball and gymnastics, provide the surgeon with far more feedback than the most sophisticated outcome instruments. In addition, simple activities of daily living such as bathing, dressing, and eating are made easier for most children, which greatly improves their self-esteem and is easily demonstrated in postoperative visits. A toe-to-hand transfer is the best procedure for reconstruction for children who have multiple missing digits resulting from traumatic amputations or congenital differences. This complex procedure will continue to be refined, but in the future may be supplanted by digital transplantation or by digital regeneration with genetically engineered tissues.

KEY POINTS

- Toe-to-hand transfer in children may be indicated after a traumatic injury or for congenital constriction ring syndrome, transverse deficiencies, cleft hand, and symbrachydactyly.
- Thumb hypoplasia in radial ray deficiency is best managed by index pollicization.
- Attention to detail is paramount in history-taking, clinical examination of the hand and foot, digital positioning, bony fixation, and postoperative support.
- Preparation of the toe and its vascular pedicle is the most challenging technical feature.

Hand and Upper Extremity Trauma

Kodi Azari • W. P. Andrew Lee • Jaimie T. Shores

In children, the upper extremity—the hand in particular—is among the most commonly injured body parts, accounting for a significant percentage of emergency department visits.¹⁻³ Because the anatomy of the upper extremity is complex and the consequences of injury are potentially serious, proper diagnosis and timely treatment are essential. Most hand injuries are minor; however, some may be limb-threatening, even life-threatening. Toddlers have a propensity for fingertip injuries, especially crush injuries in closing doors, whereas older children and teenagers have sports-related hand injuries that are often closed fractures.⁴

Care of pediatric hand injuries poses particular difficulties and pitfalls in that children are unreliable historians and often do not cooperate with the hand examination or postoperative rehabilitation. Furthermore, their developing growth plates, cartilaginous caps, and growing bones require a surgeon who is thoroughly familiar with this unique anatomy, because these sites are frequently traumatized. Fortunately, children have remarkable healing capabilities and usually recover without complications and stiffness.

ANATOMY

The anatomy of a child's hand differs from that of an adult. The differences are typical to each system and change with the age of the child.

Skin

The skin of the hand, as in an adult, includes dorsal, elastic skin and palmar, glabrous, specialized skin. The palmar skin is thicker and is connected by fascial septa to the palmar fascia, allowing traction and durability during function.

The dorsal skin is more elastic in children than in adults, allowing more swelling to occur. In infants, a larger amount of subcutaneous fat may obscure some of this swelling and some of the bony landmarks on the dorsum of the hand.

Vascular System

The vascular supply of the upper extremity originates from the axillary artery, which becomes the brachial artery distal to the axilla (Fig. 52-1). The brachial artery courses along the medial intermuscular septum and enters the antecubital fossa medial to the bicipital aponeurosis. The major branches of the brachial artery are the profunda brachii, the superior and inferior ulnar collateral arteries, and the biceps myocutaneous arteries. The artery bifurcates into the radial and ulnar arteries in the proximal forearm approximately 1 cm distal to the elbow joint.

The radial artery courses laterally over the insertion of the biceps tendon, then over the fascia of the flexor digitorum superficialis and distally between the brachioradialis tendon and flexor carpi radialis. It then crosses the snuffbox, giving off a branch that dives between the two heads of the first dorsal interosseous muscle; it is the main contributor to the deep palmar arch and also forms the princeps pollicis.

The ulnar artery courses medially in the forearm deep to the median nerve and the two heads of the flexor digitorum profundus and flexor carpi ulnaris. The artery gives off the recurrent branches at the level of the flexor digitorum superficialis origin and the common interosseous artery deep to the pronator teres. This artery later divides into the anterior and posterior interosseous arteries.

Together with the ulnar nerve, the ulnar artery enters the hand through the Guyon canal. The artery then divides and gives branches to the deep and superficial palmar arches. The superficial palmar arch is mainly supplied by and is the continuation of the ulnar artery. The arch gives off digital branches to the thumb (the first web space), the common digital branches to the three web spaces, and one branch to the ulnar side of the little finger. The common digital branches divide into radial and ulnar digital branches to the fingers. Although the vascular structures are superficial to the nerves in the palm, they become deep to the nerves in the fingers.

Nervous System

The brachial plexus gives rise to the nerves in the upper extremity (Fig. 52-2). The plexus emerges from roots C5-T2 and the first thoracic root. Occasionally, C4 and T2 contribute to the brachial plexus. The rootlets merge to form the upper, middle, and lower nerve trunks and travel in close association with the subclavian vessels. The posterior cord of the brachial plexus gives rise to the axillary nerve and the radial nerve. Just distal to the clavicle, the trunks intermingle to form the posterior, lateral, and medial cords. More distally, these structures divide to form the major peripheral nerves of the upper extremity.

The posterior cord gives rise to the axillary and radial nerves. The lateral cord gives rise to the median nerve and the myocutaneous nerve and contributes to the median nerve. The medial cord forms the ulnar nerve and also contributes to the median nerve. The superficial location of the median, ulnar, and myocutaneous nerves places them in susceptible positions for penetrating injuries, whereas the axillary and radial nerves are more commonly injured during shoulder dislocation.

Fig. 52-1 Arterial anatomy of the upper extremity.

Fig. 52-2 The brachial plexus.

The axillary nerve provides motor innervation to the deltoid muscle and sensory innervation to the lateral and dorsal aspects of the shoulder. The myocutaneous nerve innervates the brachialis, coracobrachialis, and biceps muscles. It becomes the lateral cutaneous nerve of the arm and forearm, supplying sensation to the proximal radial portion of the forearm.

The median nerve travels with the brachial artery in the arm (Fig. 52-3). The median nerve crosses the elbow in the cubital fossa, medial to the brachial artery. It then enters the forearm through the two heads of the pronator teres. The median nerve innervates the flexors of the wrist and fingers. It courses on the inferior surface of the flexor digitorum superficialis and innervates the pronator teres, flexor digitorum superficialis, palmaris longus, and flexor carpi radialis. The anterior interosseous branch innervates the flexor pollicis longus, pronator quadratus, and the two radial muscle bellies of the flexor digitorum profundus.

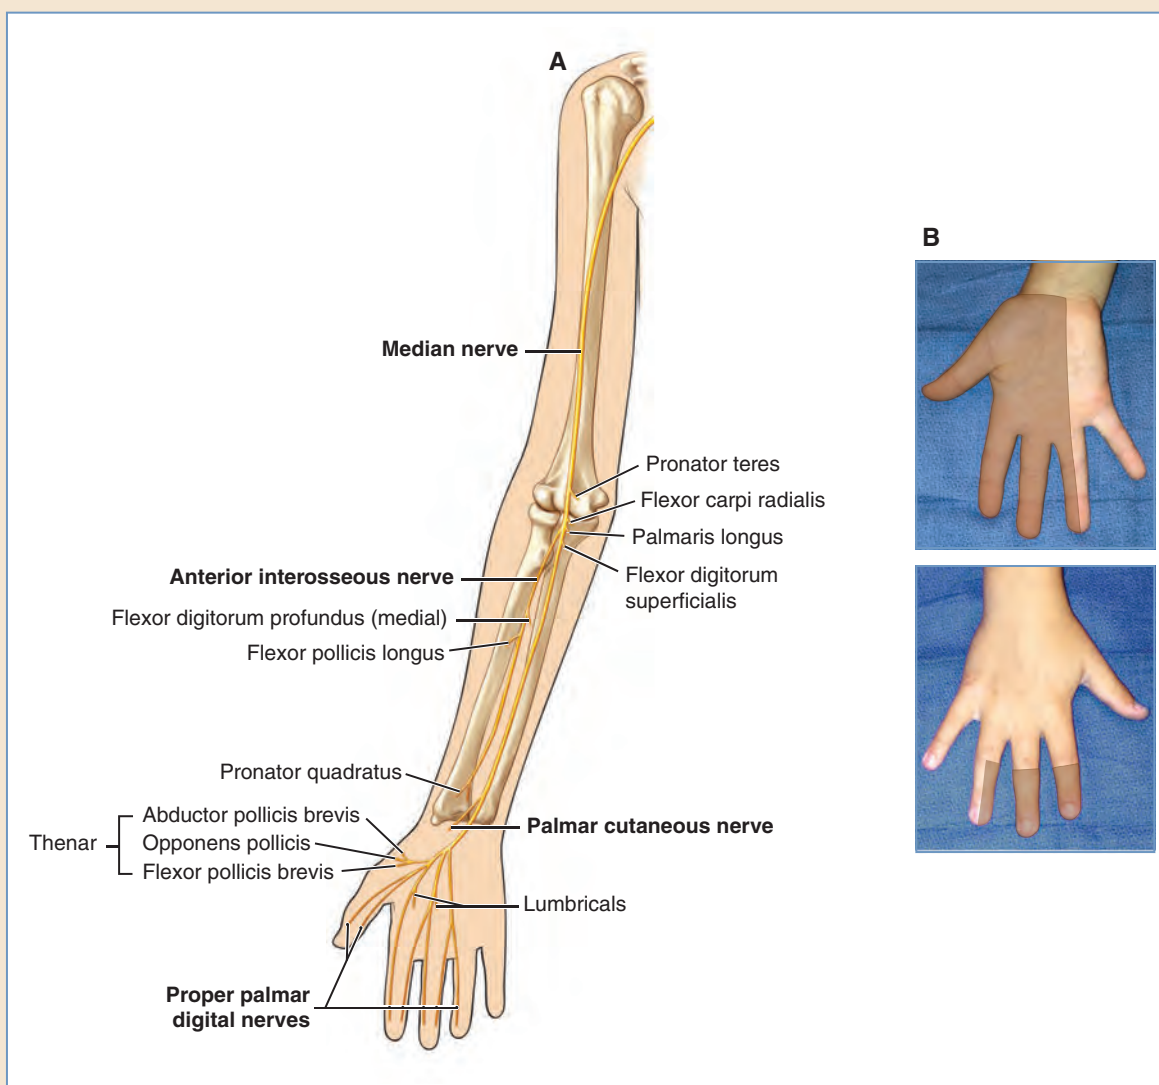

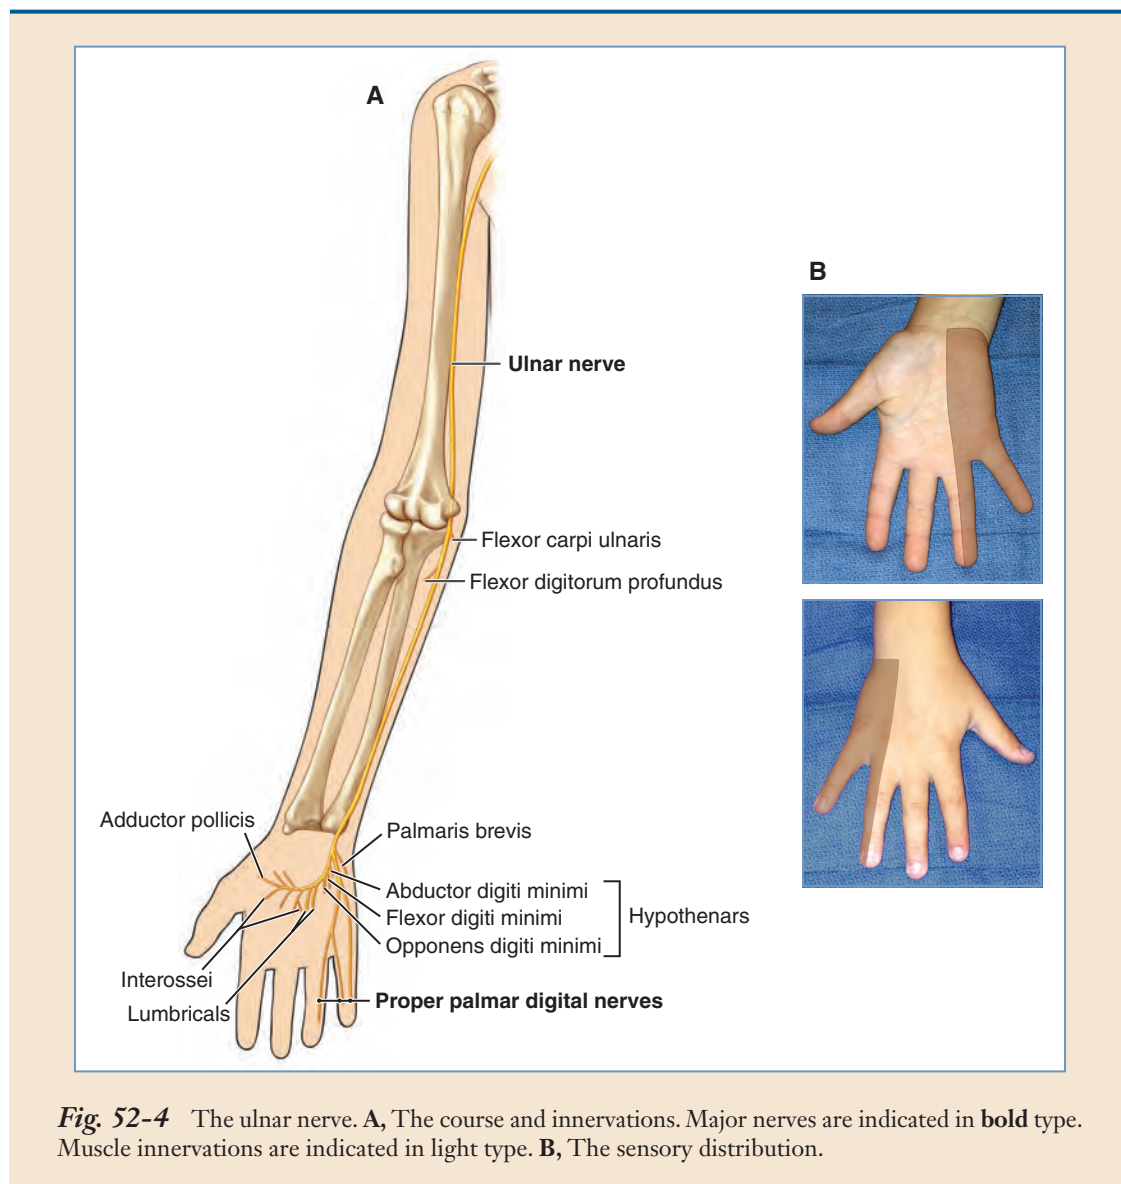

Fig. 52-3 The median nerve. **A**, The course and innervations. Major nerves are indicated in **bold** type. Muscle innervations are indicated in light type. **B**, The sensory distribution.

The median nerve then travels just beneath the palmaris longus tendon toward the palmar wrist. At this location it is quite superficial and vulnerable to injury. The nerve enters the hand through the carpal tunnel. At the level of the wrist, the median nerve motor fibers are located palmar and radial to the sensory fibers. The motor branch of the median nerve provides innervation to the thenar muscles and to the first two lumbrical muscles. The palmar cutaneous branch usually begins 6 cm proximal to the palm, travels radial to the palmaris longus tendon, and supplies sensation to the radial palm.

The ulnar nerve travels in the medial aspect of the arm (Fig. 52-4). It enters the forearm between the two heads of the flexor carpi ulnaris, having passed through the cubital tunnel on the medial aspect of the elbow. At this point, it is unprotected by any overlying musculature and is subject to trauma. The ulnar nerve runs between and innervates the flexor carpi ulnaris and the

two ulnar muscle bellies of the flexor digitorum profundus. Thus injury at this level will lead to motor deficits (the inability to flex the distal interphalangeal [DIP] joint of the small finger) and sensory deficits.

In the forearm, the ulnar nerve is topographically organized into three large and distinct bundles: the dorsal cutaneous branch, the superficial sensory branch, and the deep motor branch. Approximately 5 cm proximal to the pisiform bone, the ulnar nerve gives off the dorsal cutaneous branch, which supplies sensation to the ulnar side of the dorsal hand. The nerve enters the palm through the Guyon canal, where the superficial sensory branch splits into a common digital nerve sensory branch that gives off the common digital nerve to the fourth web space and the ulnar digital nerve to the little finger. The motor fibers (deep motor branch) of the ulnar nerve are located ulnar and dorsal to the sensory fibers and innervate all of the intrinsic muscles of the hand except those innervated by the median nerve.

Fig. 52-5 The radial nerve. **A**, The course and innervations. Major nerves are indicated in **bold** type. Muscle innervations are indicated in light type. **B**, The sensory distribution.

The radial nerve in the arm travels from medial to posteroradial and then anteriorly between the biceps and brachialis muscles (Fig. 52-5). It travels on the shaft of the humerus in the spiral groove. The nerve courses anteromedially between the brachialis and brachioradialis over the lateral epicondyle. In the arm, the radial nerve innervates the triceps, the brachioradialis, and the extensor carpi radialis longus. The nerve continues anterolaterally into the forearm and divides into two major branches: the superficial and the deep (posterior interosseous nerve). The superficial radial nerve is composed mostly of sensory branches to the radial side of the hand. It often provides motor innervation to the extensor carpi radialis brevis. The posterior interosseous nerve runs through the two heads of the supinator and innervates the supinator, extensor carpi ulnaris, extensor digitorum communis, abductor pollicis longus, extensor pollicis brevis, extensor pollicis longus, extensor indicis proprius, and the extensor digiti minimi muscles.

The sensory innervation of the hand is supplied by all three nerves. In the fingers, the digital nerves lie palmar to the arteries on the radial and ulnar sides of the flexor tendon sheath. Therefore, when a penetrating injury leads to pulsatile bleeding, both the nerve and the deeper artery have probably been injured. At the level of the DIP joint, the nerves trifurcate into terminal branches to the tip of the fingers.

Muscles and Tendons

Flexor Muscles and Tendons

The muscles on the flexor aspect of the forearm can be divided into deep and superficial compartments (Figs. 52-6 and 52-7). The tendons insert onto the wrist or digits. The superficial compartment contains the palmaris longus, flexor carpi radialis, and flexor carpi ulnaris muscles. Proximally, the pronator teres is the deeper muscle belly. The flexor digitorum superficialis lies

Fig. 52-6 The palmar muscles of the forearm.

deep to this layer. The flexor digitorum superficialis arises from two heads and has four distal tendons that cross the wrist and flex the proximal interphalangeal (PIP) joints of the index, middle, ring, and little fingers. The tendons of the middle and ring fingers are more superficial than those of the index and little fingers at the level of the wrist. After the tendons form the Camper chiasm (through which the tendon of the flexor digitorum profundus travels), they insert into the middle phalanx of the fingers.

The deep muscle compartment in the forearm includes the flexor digitorum profundus and the flexor pollicis longus. Because these are in close contact with the bones of the forearm and the interosseous membrane, they are at the highest risk of having ischemic injury in compartment syndrome. The flexor digitorum profundus has four tendons, which cross the wrist and flex both the PIP and DIP joints of the respective fingers. Fascial connections are present between these tendons in the wrist and proximal to the wrist itself. The tendons of the flexor digitorum profundus insert into the base of the distal phalanx. In about a third of hands, the flexor digitorum superficialis to the little finger is absent. Usually, this deficit is unilateral. In the deep compartment of the distal forearm, the pronator quadratus spans the palmar aspect of the distal radius to the ulna. The flexor pollicis longus travels on the radial aspect of the carpal tunnel, then through the thenar eminence and into the fibroosseous canal to insert into the base of the distal phalanx of the thumb.

Extensor Muscles and Tendons

The extensor (dorsal) forearm contains the extensors of the wrist and the extrinsic extensors of the fingers (Figs. 52-8 and 52-9). The extensors arise from a common origin on the lateral epicondyle of the humerus. Arising deep and distally are the extensors and abductors of the thumb. At the level of the wrist, the extensor tendons travel through well-defined fascial compartments under the extensor retinaculum. There are six extensor compartments. The first compartment includes the abductor pollicis longus and extensor pollicis brevis. Although a particular pathology affects this compartment in adults, it is extremely rare in children. The second compartment includes the wrist extensors: the extensor carpi radialis longus and the extensor carpi radialis brevis. The third compartment contains the extensor pollicis longus, which extends the thumb and inserts on the thumb distal phalanx. The fourth dorsal compartment includes the finger extensors—the

Fig. 52-8 The dorsal muscles of the forearm.

Fig. 52-9 Cross-section of the wrist at the distal forearm.

tendons of the extensor digitorum communis and the extensor indicis proprius. The fifth compartment includes the extensor digiti minimi, and the sixth includes the extensor carpi ulnaris.

Intrinsic Muscles

The intrinsic muscles of the hand are those that originate and insert within the hand. These include the lumbricals and the palmar and dorsal interossei. The four dorsal interossei are abductors of the fingers. The three palmar interosseous muscles are adductors. These muscles also flex

Fig. 52-10 The bones of the hand and wrist.

the metacarpophalangeal (MP) joints and extend the interphalangeal joints of the fingers. The muscles of the thenar and hypothenar eminences include the following:

- Abductor pollicis brevis
- Flexor pollicis brevis
- Opponens pollicis
- Abductor digiti minimi
- Flexor digiti minimi
- Opponens digiti minimi

The intrinsic muscles also include the adductor pollicis.

Bones and Joints

The bones of the hand and wrist include the radius and ulna, the carpal bones, the metacarpals, and the phalangeal bones (Fig. 52-10). There are eight carpal bones: the proximal carpal row consists of the scaphoid, lunate, and triquetrum; the distal carpal row includes the trapezium, trapezoid, capitate, and hamate; and the pisiform is a sesamoid bone within the tendon of the flexor carpi ulnaris.

The wrist joint comprises the distal radioulnar joint, radiocarpal joints, intercarpal joints, and the carpometacarpal joints. In each finger the proximal joint is the MP joint; the PIP and DIP joints are more distal.

PATIENT EVALUATION

As in all cases of trauma, the whole patient should be evaluated first, and the management of the injuries should be prioritized accordingly. A pediatric patient's general condition can rapidly deteriorate; therefore urgent problems or injuries should be addressed expeditiously. The primary goals of the initial evaluation in the emergency department are the following:

1. To determine what structures are injured
2. To determine whether the injury requires urgent or elective operative treatment
3. To provide the patient and parents with information on the injury severity, management goals, and expected prognosis
4. To assure the patient and parents that the injury will be cared for by an experienced, competent, and compassionate surgeon

We do not wear white coats during the consultation and find it very helpful to have the child sit in the parent's lap for reassurance. Beginning the evaluation slowly, gently, and in a playful manner is critical to secure the child's trust. Distraction techniques can be useful to make the child feel more at ease. In our institution, for example, we routinely show popular cartoon videos in each examination room during the evaluation. However, occasionally, a child is uncooperative to the extent that an evaluation cannot be performed. Intravenous sedation may be necessary in these situations.

A formal evaluation consists of a history, physical examination, and laboratory testing as necessary. The history should include specific information such as the mechanism of hand trauma, the time of injury, and the place of occurrence. A brief medical history is obtained to determine allergies and general conditions such as diabetes. A past surgical history is obtained, as well as any family history of medical illnesses, including anesthesia issues. Obtaining a social history helps in understanding the child's social support system and exposure to tobacco, alcohol, and drugs.

The physical examination should start with observation, followed by palpation, which can provoke apprehension and pain. Especially in children, this part of the examination is invaluable. We routinely first examine the unaffected extremity. This technique calms the patient significantly by helping the child understand what to expect. Next, before evaluating the injured extremity, the surgeon should reassure the child that the examination will stop if "it hurts too much."

A vascular assessment should be performed early in the examination, because vascular compromise will require urgent operative treatment. Vascularity can be evaluated by observing the color and capillary refill in the fingers. A temperature assessment is useful, especially a comparison between the injured and uninjured extremity. Pulses are palpated and pulp turgor assessed.

Sensation is sometimes more difficult to assess and requires the cooperation of the patient. This is not always possible, especially in small children. If possible, static and moving two-point sensation, paresthesias, and dysesthesias are documented. In very young children who cannot reliably communicate, alternative means can be used to assess nerve injury. In the presence of a nerve laceration, the skin overlying the distribution of the lacerated nerve feels dry, whereas uninjured regions are moist. A water immersion test can help to confirm a nerve injury (see Acute Nerve Injuries).

Motor function should be evaluated in the specific nervous distributions. Fractures and injuries to other soft tissues may affect the motor unit function performance in a nerve distribution, even though the nerves and neuromuscular structures are intact.

Swelling, deformity, and spontaneous use are noted. Palpation may help to localize an injury to bones and joints, especially in the wrist. Movement may be less sensitive and specific.

Myotendinous units can be examined in cooperative patients with no bony/joint injury. The flexors and extensors should be examined separately.

Flexor Tendon Examination

An examination of the flexor tendons of digits comprises the following four components:

1. Active range of motion
2. Observation at rest
3. A forearm squeeze test
4. The tenodesis effect

Of these tests, only the active range-of-motion test cannot be performed with the patient under general anesthesia.

Active Range-of-Motion Test

In an awake and compliant patient, the flexor digitorum profundus and flexor digitorum superficialis tendons can be examined separately. To examine the flexor digitorum superficialis, the fingers are examined individually by restraining the other four in extension and then the patient is asked to bend them in at the PIP joint. This maneuver neutralizes the flexor digitorum profundus, whose tendons are connected distally. The ability to fully flex at the PIP joint indicates a competent flexor digitorum superficialis tendon. The flexor digitorum profundus can then be examined by inhibiting flexion at the PIP joint of the finger and allowing flexion only at the DIP joint. The ability to flex at the DIP joint indicates an intact flexor digitorum profundus tendon. This examination is repeated, with gentle resistance applied. If attempted flexion is painful, a tendon injury should be suspected.

Observation at Rest

With the patient relaxed or under anesthesia, the posture of the digits can be observed. The normal cascade is of increasing flexion, beginning with the index finger and progressing to the small finger.

Forearm Squeeze Test

To test for a distal forearm injury, tendon continuity can be assessed by placing pressure on (squeezing) the proximal forearm. Intact myotendinous units will transmit the force and cause digit flexion. However, partial tendon lacerations can be misleading, because they may result in finger flexion.

Tenodesis Effect

To assess muscle-tendon continuity, the examiner evaluates the tenodesis effect (Fig. 52-11). Gentle, passive flexion and extension of the wrist cause passive digit extension and flexion, respectively, if the tendons are intact. Flexion should appear in the normal cascade.

Extensor Tendon Examination

An extensor tendon examination is composed of three basic components:

1. Active range of motion
2. Observation
3. The tenodesis effect

The most informative of the three examinations is an active range-of-motion evaluation. In a cooperative patient, each extensor muscle unit should be examined independently. The hand is

Fig. 52-11 The tenodesis effect in a patient with a zone II flexor digitorum superficialis and flexor digitorum profundus laceration. The small finger digital cascade is absent with the wrist passively extended.

allowed to rest comfortably, and the thumb and each finger is individually examined for MP, PIP, and DIP extension.

If it is determined that the patient is best cared for in the operating room, the injury should not be exposed in the emergency department. Except for superficial injuries, probing wounds in the emergency department is ill advised; without loupe magnification, tourniquet control, proper pain control, and adequate lighting it can prove harmful. Most decisions on the need for operative exploration can be based on a thorough history and physical examination.

FRACTURES IN THE PEDIATRIC HAND

Approximately 10% to 15% of all childhood injuries involve skeletal trauma.⁵ The growing skeleton often has a different mechanism of injury and a different capacity to heal and remodel. Therefore the treatment may vary with age and be different from that of an adult. Fractures and dislocations in the hand are less common in children than in adults. Fractures in children will heal faster than those in adults and will rarely develop stiffness after immobilization.

The growth plate (the epiphyseal plate and/or epiphysis) is the center of long-bone growth through the essential mechanisms for endochondral ossification.⁶ The anatomy of the epiphyseal plate is shown in Fig. 52-12. The primary function of the epiphysis (physis) is longitudinal and latitudinal growth of long bones. In the hand, the metacarpal and phalangeal bones are long bones. These bones have an epiphysis only on one end. The phalangeal physis is at the proximal end of the phalanx. The metacarpal physis is at the distal edge. Therefore most of the growth in the finger surrounds the MP joint. This is not the case in the thumb metacarpal, in which the epiphysis is located proximally. This difference may be helpful in distinguishing between a thumb and a finger in certain congenital deformities. Fig. 52-13 shows the time of appearance and fusion of the epiphyseal centers. An easy way to remember the times of epiphyseal center appearance is illustrated in Fig. 52-14. The epiphyses appear and close earlier in girls. A second epiphysis is sometimes present at the distal end of the first metacarpal or at the proximal end of the index metacarpal. This is referred to as a *pseudoeiphysis* and is sometimes confused with a fracture. These usually fuse early. Comparing radiographs of the affected side with those of the uninjured side can be helpful, because the epiphyses are irregular and individual differences occur. An atlas may not be readily available for reference.

Fig. 52-12 Anatomy of an epiphysis.

Fig. 52-13 The ages of epiphyseal center appearance and physeal fusion.

Fig. 52-14 Carpal bone appearance. The arrow denotes the usual sequence of carpal bone appearance: capitate, hamate, triquetrum, lunate, scaphoid, trapezium, trapezoid, and pisiform.

Fig. 52-15 The Salter-Harris classification system of epiphyseal fractures. (*I*, Separation of the epiphysis from the metaphysis; *II*, a fracture through the epiphyseal plate and the metaphysis; *III*, a fracture through the plate and the physis; *IV*, a fracture through the metaphysis, the epiphyseal plate, and the physis; *V*, a severe injury through the epiphyseal plate.)

Injuries involving the physis constitute about a third of all pediatric hand fractures.¹ These are areas of minor resistance; thus fractures can occur through them. Often, they are near insertions of ligaments or tendons. In the MP joint, the collateral ligament originates from the metacarpal epiphysis, and its cord portion inserts in the epiphysis of the proximal phalanx and the palmar plate. In the PIP joint, the collateral ligament inserts both into the epiphysis and into the metaphysis.

Evaluation

Radiographs should be obtained for all suspected fractures in the emergency department if the patient's general condition permits. Deformity may only be assessed with a physical examination, and patients should be examined clinically first. A rotational deformity especially may not be ap-

preciated on radiographs and is evaluated by observing the direction of the fingertips when the fingers are slightly flexed and comparing them with the uninjured side. Another technique is to examine the direction of the nail. This is often the critical factor in deciding treatment.

The evaluation and treatment of associated soft tissue injuries is critical to the healing of the fractures.

Classification

Fractures should be classified based on the following:

- 1. The anatomic position (that is, the bones involved and the area involved, such as the metaphysis)
- 2. Whether the fracture involves the articular surface, with or without dislocation
- 3. Whether the fracture is open or closed

The Salter-Harris classification⁷ is a very useful system for describing fractures involving the epiphysis (Fig. 52-15). This classification not only provides a means for communication but also aids in determining prognosis. Type I injuries include separation from the metaphysis. Salter-Harris type II is the most common injury and usually carries a benign prognosis.⁷ In this case, the force causing the fracture travels through the epiphyseal plate and the metaphysis. Type III fractures extend through the plate and the physis. Type IV fractures extend through the metaphysis, the epiphyseal plate, and the physis. Type V is a severe injury through the epiphyseal plate. The implication of this type of injury is a propensity to develop fusion of all or part of the growth plate. If the whole growth plate is affected, growth may be arrested. If only a part is affected, there is a risk of an angulatory deformity, because one area of the growth plate will grow more than the other. The parents should always be warned that growth might be affected. Although this is relatively rare, we do not have the means to accurately predict which fractures will undergo early fusion.

Table 52-1 Gustilo Open Fracture Classification	
Type	Characteristics
I	A clean puncture wound of 1 cm or less No muscle contusion or soft tissue involvement No crush component
II	A laceration larger than 1 cm Without extensive soft tissue damage, flaps, or avulsions A minimal-to-moderate crush component
III	Extensive damage to soft tissues A high-velocity or severe crush injury Skin, muscle, or vascular injury
IIIA	Adequate soft tissue coverage
IIIB	Bone exposure and periosteal stripping
IIIC	An arterial injury requiring repair

Classically, open fractures have been described using the Gustilo classification⁸ (Table 52-1). Although this system was initially described for lower extremity injuries, the nomenclature has been adopted for upper extremity open injuries as well. Type I injuries are fractures with a wound of 1 cm or less. Type II fractures are open fractures with a wound larger than 1 cm but without extensive soft tissue damage. Type III fractures are associated with extensive soft tissue damage and have three categories: type IIIA has adequate soft tissue coverage, IIIB is associated with bone exposure and periosteal stripping, and IIIC has an arterial injury requiring repair.

Treatment

As in all hand fractures, treatment consists of reduction and fixation. Most fractures in the hand and wrist can be reduced in the emergency department, with the patient under a digital or wrist block. A splint or cast is applied. Minor degrees of angulation may correct with remodeling and should require no further treatment. This is especially true for displacement in the direction of joint motion. The younger the child, the greater the remodeling potential. Correction of rotational fractures is less reliable. Scissoring of the finger or abduction in a border digit after reduction, necessitates open reduction. Operative management is probably required. Epiphyseal injuries that are not easily manipulated should probably be treated in an open manner. In general, multiple attempts at reduction can cause permanent epiphyseal damage and are discouraged. After about a week, the fracture has begun to heal, and more damage can be done by trying to manipulate these fractures in a closed fashion. Immobilization on the whole is more difficult in children than in adults, particularly in small children, in whom a long cast may be required for a finger fracture. Open reduction is indicated when closed reduction cannot be achieved. Reductions that can be obtained but not maintained are considered unstable and require some manner of fixation.

The most common fractures are phalangeal—more often occurring distally. Most distal phalangeal fractures result from a crush injury to the fingertip and include soft tissue injury. The nail bed should be repaired with fine absorbable suture. Rarely, the nail bed becomes interposed in an epiphyseal fracture (Seymour fracture), necessitating an open reduction (Fig. 52-16). Seymour fractures that go unrecognized can result in malunion or nonunion, osteomyelitis, and permanent nail deformity. This injury should be considered with any apex dorsal fracture through the distal phalanx physis.

Phalangeal shaft fractures can be transverse, oblique, spiral, or comminuted and are treated according to the deformity and stability after closed reduction. Salter-Harris type II fractures of the proximal phalanx are common, especially in the little finger.⁷ These can usually be reduced in a closed fashion using a digital block. Placing a pen between the ring and little fingers may be helpful for reducing the fracture by stabilizing the proximal fragment (Fig. 52-17). The distal finger is then adducted toward the ring finger, bringing the distal fragment back into place (see Fig. 52-17). Metacarpal fractures in children usually do not require operative treatment. Metacarpal neck fractures are fairly common but rarely require surgery.

Fractures of the carpal bones are relatively rare, although scaphoid fractures occur at any age. Because many of the carpal bones are only partially ossified, these fractures often are difficult to diagnose and are classified as wrist sprains. In children, they are usually treated conservatively but with a longer immobilization period (6 weeks). As in adults, fractures of the scaphoid are probably the most common; the diagnosis is made from a history of a fall, often on an outstretched hand, and an examination that elicits tenderness in the area of the snuffbox. As in adults, such fractures in children, even if only suspected, should be treated with a thumb spica splint or cast, followed by repeat radiographs in 2 weeks. The incidence of nonunion is lower in children because of increased stability and their superior biologic factors.

Fig. 52-16 Correction of a Seymour fracture. **A**, Incisions to reflect back the eponychial fold. **B**, Germinal matrix caught inside the fracture. **C**, Germinal matrix delivered out of the fracture gap. **D**, Germinal matrix repaired to the terminal tendon. **E**, Eponychial fold incisions repaired with cyanoacrylate glue. **F**, A preoperative radiograph shows an apex dorsal angular deformity through the physis. **G** and **H**, Postoperative radiographs show the pins in place.

Fig. 52-17 Closed reduction of the proximal phalanx of the little finger using a pin to stabilize the proximal fragment while the distal part of the finger is adducted toward the ring finger. With this adduction pressure, the fracture will realign.

The most commonly fractured bone in children is the radius; 82% of these involve the distal third of the bone.⁹ A general classification of these fractures includes the following types: physeal, torus, greenstick, and complete. A reasonable closed reduction is usually obtained, and growth disturbances are rare, even with physeal involvement. Some degree of angulation can be corrected with growth and remodeling, especially when the fracture line lies close to the growth plate. With more proximal involvement of both bones, the reduction can be more difficult and require an open method.

DISLOCATIONS

Dislocations can be associated with fractures, or they may be purely soft tissue injuries. They are classified as simple (reducible) or complex (irreducible, usually as a result of soft tissue interposition). Similar to fractures, they may be open or closed. Dislocations in a child's hand have to be distinguished from fractures that include the epiphyseal plate. This distinction can only be made with radiographs.

The MP and interphalangeal joints tend to dislocate dorsally (that is, the distal bone dislocates dorsally). Most simple dislocations in the hand can be reduced in the emergency department. In the thumb, an often-irreducible fracture/dislocation is the Bennett fracture equivalent. This is a fracture dislocation of the base of the thumb. Compared with adults, children often have a larger fragment of bone, and the epiphysis is not always clearly involved. However, this fracture behaves like an adult Bennett fracture in that the distal/dorsal fragment is pulled proximally and radially by the tendon of the abductor pollicis longus, and the proximal/palmar fragment remains attached to the palmar oblique ligament of the joint. These fractures are surprisingly difficult to reduce and must be held in the reduced position.

Conservative treatment consists of 3 to 4 weeks of immobilization. The younger the child, the less time necessary for immobilization. The hand should be in the intrinsic-plus position within the cast, with the MP joints at 70 or 80 degrees of flexion and the interphalangeal joints in full extension. Operative treatment for fracture reduction and stabilization is usually minimal; the surgeon should disturb the growth plates as little as possible. Plates are therefore rarely used; smooth K-wires are the mainstay of treatment.

TENDON INJURIES

Flexor Tendon Injuries

The treatment and repair of flexor tendons in children differs from that in adults in these ways^{10,11}:

- Especially in small children, initial immobilization and later early mobilization according to adult protocol may be difficult, if not impossible.
- Possibly for this reason, but also because of the more rapid fibroblast proliferation in children, contractures after repair are often more pronounced and more difficult to overcome.
- Because of the relatively small size of the different structures, the technical aspects of the repairs are more challenging.

The zone of injury is significant both for repair and for functional outcome. The classification system, a modification of the Verdan system,¹² is a useful tool for relaying information regarding an injury (Fig. 52-18). In this system, flexor zone I includes the flexor digitorum profundus alone and its insertion into the distal phalanx. Zone II includes the area beneath the fibroosseous sheath, which includes both the tendon of the flexor digitorum profundus and the flexor digitorum superficialis. This area is called *no-man's land* because of the poor postoperative functional

Fig. 52-18 Verdan zones of flexor tendon injury. (See the text for descriptions of all zones.)

results after tendon repair in this area. Zone III is the area between the carpal tunnel and the entrance to the fibroosseous sheath. This area contains the origins of the lumbrical muscles. Zone IV is the area of the carpal tunnel. Zone V is the area proximal to the carpal tunnel and includes the myotendinous junctures.

In the thumb, zone I is similar to that in the fingers and includes the edge of the retinaculum to the insertion of the flexor pollicis longus. Zone II includes the area under the flexor retinaculum of the thumb from the neck of the metacarpal to the neck of the proximal phalanx. Zone III includes the tendon proximally in the thenar eminence. These zones relate to the level of tendon injury and not to skin laceration.

The skin injury does not always correlate with the level of tendon injury. The level of tendon injury depends on the degree of finger flexion at the time of injury. The injury is repaired in the operating room, with exploration of the digital nerves. Better results are achieved if the repair is done within 10 days to 2 weeks after the injury. The skin incisions (for example, a zigzag Bruner incision,¹³ a Z-plasty incision, or midlateral incisions in the fingers), as in all palmar injuries, should allow healing without longitudinal contraction.

Flexor tendons should be repaired with a core suture so that gliding is not hindered. However, the type of suture used is controversial and depends on the surgeon's preference. Most surgeons supplement the core sutures with a running epitendinous suture. This has been shown to increase the strength of the repair in addition to "tidying" the repair edges. Rarely, an injury is infected or crushed to a degree that a delayed repair is deemed necessary.

After the tendon repair, protected immobilization is the recommended rehabilitation principle. In young children, a long-arm "clamdigger" cast is placed, with the elbow in 95 degrees of flexion, the wrist in 0 to 20 degrees of extension, the MPs in 60 to 70 degrees of flexion, and the interphalangeal joints in full extension. A short-arm clamdigger cast is applied for older children. We routinely place thick gauze padding from the MP joints to the fingertips and remove the

padding once the cast has hardened. This maneuver provides space for protected active range of motion for the digits within the confines of the cast.¹⁴⁻¹⁷

The extremity is immobilized for 4 weeks. In children younger than 3 years of age, no further immobilization is required. In patients older than 3 years of age, a dorsal blocking splint is worn during the daytime (to prevent accidental forceful digit extension) for an additional 3 weeks. Thereafter, our hand therapists teach the parents flexion and extension play therapy exercises so that they can begin a home therapy program. If by postoperative week 8 the child is unable to fully extend the digit, a formal hand therapy program is initiated with nighttime extension splinting. In adults, when adhesions limit digital function and an ample course of hand therapy has reached maximal usefulness, a flexor tenolysis is considered. In our experience, tenolysis in children is technically most challenging, and only minimal postoperative improvement is expected. Therefore we do not routinely perform flexor tenolysis for children younger than 10 years of age.

Extensor Tendon Injuries

The anatomy of the extensor mechanism—especially in the finger—is complex and very difficult to reproduce correctly. As in the diagnosis and treatment of flexor tendon injuries, extensor tendon injuries are classified into Verdan zones¹² (Fig. 52-19). Zone I is the area over the DIP joint, zone II is the area over the dorsum of the middle phalanx, zone III is over the PIP joint, zone IV is over the proximal phalanx, zone V is over the metacarpophalangeal joint, zone VI is over the metacarpal, zone VII is over the carpals, zone VIII is over the proximal wrist, zone T-I is at the interphalangeal joint, zone T-II is over the proximal phalanx, zone T-III is at the metacarpophalangeal joint, zone T-IV is at the metacarpal, and zone T-V is over the carpometacarpal joint. The areas of injury proximal to the finger are more easily reconstructed and can have very good functional results, especially in children.

Fig. 52-19 Verdan zones of extensor tendon injury. (See the text for descriptions of all zones.)

Zone I injuries cause an inability to extend the distal phalanx, resulting in a mallet finger. The most common mechanism of injury is jamming of a fingertip. These often occur in sporting activities like football, volleyball, and basketball. The injury can result in a tendon rupture or avulsion fracture of the extensor tendon insertion into the distal phalanx. In children, bony mallets are more common than nonbony mallets and often involve the epiphyseal plate, because this is the area of minimal resistance. In a typical closed mallet finger deformity, the terminal extensor tendon is thin and not able to accept suture. Furthermore, the ruptured ends do not usually retract far. Therefore most of these injuries can be treated by closed reduction and 6 to 8 weeks of continuous splinting with extension of the DIP joint. Avulsion injuries with a dorsal bony fragment that is a third of the articular surface, or if articular subluxation and instability are present, operative intervention is indicated to restore the articular architecture. Following the 6- to 8-week immobilization period, gentle protected digital range-of-motion exercises are initiated, and the DIP joint is splinted at night for another 2 to 4 weeks. However, if after 6 to 8 weeks of immobilization an unacceptable extension lag persists, up to 6 more weeks of uninterrupted splinting may be required.

Zone II injuries are similar to those in zone I and result in a flexion deformity of the DIP joint. The extensor mechanism is more robust in this region compared with that of zone I, and clean lacerations can usually be repaired with 5-0 nylon horizontal mattress sutures. Segmental losses are more difficult to repair and require reconstruction. Postoperatively, the DIP joint is immobilized by K-wire or splinting for 4 to 6 weeks.

Zone III is located over the PIP joint; it is a complex region where the components of the extensor mechanism merge, including the central slip and the lateral bands. Injuries in this area can be caused by laceration, avulsion of the middle phalanx dorsal articular surface, and PIP fracture dislocations. Injuries are often misdiagnosed, and if left untreated, result in a deformity in which the head of the proximal phalanx protrudes through the extensor hood, and the lateral bands progressively palmarly displace. This progressive deformity results in a boutonnière (buttonhole) deformity with a flexed PIP and a hyperextended DIP posture (Fig. 52-20).

With acute open injuries, the PIP joint capsule requires irrigation and separate closure. The central slip is repaired or reattached to the middle phalanx, and the lateral bands are medialized. The digit is immobilized for 1 week by placing the MP joint in 30 degrees of flexion, the PIP joint in full extension, and the DIP joint is left free to allow full motion. After 1 week, only the PIP joint is immobilized in full extension for 5 weeks.

Closed ruptures of the central slip are best treated by PIP extension splinting for 4 to 6 weeks. With the DIP joint free, the patient can pull the lateral bands up while flexing the DIP joint, improving the clinical result.

Injuries in zones IV and V are treated similarly to those in zone III. The tendon is repaired with 4-0 or 5-0 nylon sutures with a horizontal mattress or figure-of-eight technique. For best

Fig. 52-20 A chronic boutonnière deformity from an untreated central slip injury.

postoperative results, lacerations of the index and small finger extensor indicis proprius require repair despite the presence of a competent extensor indicis proprius and extensor digiti quinti tendons. Postoperatively, the repair is protected by immobilization for 3 to 4 weeks. Although in adults there has been a trend toward early active motion, this is usually difficult to accomplish in children; it is also unnecessary.

Injuries in zones VI and VII are treated similarly. However, zone VII injuries lie within the fibroosseous extensor compartments and can be challenging to manage. Tendons are repaired with 4-0 nylon or polyester suture using a figure-of-eight or modified Kessler technique.¹⁸⁻²⁰

Thereafter, the repair is passively tested to ensure there is no impingement through the canal. Significant excursion obstruction requires excision of part of the extensor retinaculum, or, if necessary, the tendon can be transposed outside of the canal. Postoperatively, the repair is protected by immobilization of the wrist for 4 weeks in 30 degrees of extension and the MP joints in 45 degrees of flexion, followed by protected passive range-of-motion exercise.

Zone VIII injuries can occur at the myotendinous junction or involve the muscle bellies. Similar to the other zones, nonabsorbable suture with a modified Kessler figure-of-eight technique is used for repair. To add strength to the repair, the muscle epimysium is included in the suturing. Postoperatively, the wrist is immobilized in 30 degrees of extension for 4 to 6 weeks, followed by passive range-of-motion exercises.

FINGERTIP INJURIES

Fingertip traumas are among the most common hand injuries, especially in toddlers.^{4,21} Young children's probing fingers are often injured in house and car doors, bicycle chains, and home exercycles.^{22,23} Recognition and proper management are essential for maintaining hand function and preventing disability. Surgical management should attempt to preserve length and restore sensibility.

The fingertip is a specialized end organ that involves all structures distal to the insertion of both the flexor digitorum profundus and the terminal extensor tendon (Fig. 52-21). Tissues include the nail plate, nail bed, distal phalanx, subcutaneous fat, nerves, vessels, lymphatics, and skin. The germinal matrix gives rise to 90% of the nail plate, which is an epidermal structure consisting of keratinized squamous cells.²⁴ The nail plate provides improved pulp sensation and stabilization and serves a protective function. The nail plate and distal phalanx form a protective

Fig. 52-21 Anatomy of the fingertip.

sandwich for the nail bed. The nail bed adheres to the nail plate by longitudinal interdigitating ridges produced by the sterile matrix. The nail grows at the rate of 0.1 mm per day and requires nearly 6 to 9 months to achieve full growth.²⁴ After a traumatic injury, nail growth is halted for 3 weeks, followed by a 7-week period of increased nail formation.²⁵ Most injured nails achieve their final aesthetic appearance after approximately 1 year.

The fingertip is highly vascularized, densely innervated, and adapted for pinch, grasp, and manipulative functions. The specialized palmar glabrous skin contains a series of ridges (fingerprints) that provide a nonslip surface that is stably attached to the distal phalanx through dense, vertically oriented septa.²⁶ The finger pulp contains fibroadipose tissue that serves a padding function and is compartmentalized by the vertically oriented septa. Bilateral digital arteries and nerves traverse the soft tissues and arborize into the pulp. The digital nerves run palmar to the digital arteries and trifurcate near the level of the DIP joint, sending branches to the paronychium, fingertip, and palmar pulp.²⁷

Hematoma and Nail Bed Injuries

Trauma to the nail bed includes lacerations, crush injuries, avulsions, and hematomas. Injuries that involve the germinal matrix may result in nail absence, whereas injuries to the sterile matrix can cause nail plate deformity.

Hematoma

An injury to the fingertip can result in a nail bed laceration and a collection of blood beneath the nail plate, with the development of a painful subungual hematoma that can potentially compromise the survival of the nail bed. If the hematoma size is more than 25% of the nail plate and a distal phalangeal fracture is evident, removal of the nail plate, followed by inspection, is recommended.²⁸ However, some authors advocate that the decision to remove the nail plate should not be based on the percentage of hematoma, but on whether the nail edges are intact.²⁹ If the nail edges are intact, simple evacuation of the hematoma is sufficient. However, if blood has undermined the nail plate and the edges are not adherent or the nail is broken, the nail plate should be removed.³⁰

To evacuate a hematoma, the digit is prepared and draped in a standard surgical fashion and anesthetized by a finger block with 1% plain lidocaine. A battery-powered disposable ophthalmic cautery device, available in most emergency departments, can be used to burn a hole in the nail plate; alternatively, a heated paper clip can be used (Fig. 52-22). Care is required to prevent injury to the underlying nail bed, and the hole should be large enough to allow continued drainage of the hematoma.

Fig. 52-22 Evacuation of a subungual hematoma with a handheld disposable ophthalmic cautery device.

Fig. 52-23 A, A malaligned distal phalanx fracture. B, K-wire fixation.

Nail Bed Lacerations

Nail plate deformities can persist if trauma to the nail bed is not repaired anatomically. Radiographs of the distal phalanx and the nail bed are obtained to assess the anatomy. Most injuries can be comfortably addressed in the emergency department. After the patient is prepared and anesthetized with a digital block, a proximal phalanx finger tourniquet is applied for hemostasis.³¹ The nail plate can be gently separated from the nail bed using a Freer elevator or Iris scissors, with the tips pointing up, and proceeding from distal to proximal. Under loupe magnification, the nail bed is inspected and lacerations repaired with 6-0 or 7-0 absorbable plain gut sutures. The nail plate is cleaned with povidone iodine (Betadine) solution and irrigated with sterile saline solution. The fibrous undersurface attachments are scraped off. The nail plate is then replaced to stent open the eponychial fold, to provide protection for the nail bed, and to serve as a splint for distal phalanx fractures. If the native nail plate is not available, a nail-shaped stent can be fashioned from the aluminum suture package. The nail plate or stent should be secured with 5-0 chromic sutures, though this is frequently not required, and covered with nonadherent dressings.

Associated distal phalanx fractures are common findings with nail bed lacerations. Small tuft fractures do not require fixation, and the replacement of the nail plate serves as an acceptable splint. Larger, displaced fragments may be fixed with 0.028-inch K-wire (Fig. 52-23). Open fractures should be irrigated with sterile saline solution, reduced as best as possible, immobilized with a splint or K-wires, and treated with antibiotics. To best immobilize the distal phalanx, a splint is fashioned that includes the DIP joint; this is worn for 2 to 3 weeks or until the pain subsides.

Fingertip Amputations

The goals for the treatment of fingertip amputations are to preserve functional length, to restore adequate sensation, and to regain pain-free range of motion. Most surgeons agreed that preserving thumb length is critical; however, they agree less about the value of maintaining length in the other digits. Although numerous techniques have been described for fingertip reconstruction, ranging from soft tissue closure by secondary intention to microsurgical replantation, each injury should be considered individually and treatment plans made on a case-by-case basis. Several schemes have been proposed to help categorize fingertip injuries.^{8,32-34} The Allen classification⁹

of fingertip injuries is a simple and easy-to-apply system that categorizes amputations by the level of amputation (Fig. 52-24). Table 52-2 offers treatment options for each amputation level. To help better describe injuries, the Allen classification can be further divided by the planes of angulation (transverse, dorsal oblique angulation, and palmar oblique angulation).

Allen type I injuries involve only the skin and pulp of the distal digit. Children have remarkable healing potential, and these amputations can be appropriately and conservatively managed with excellent return of sensibility and cosmesis. Wound care consists of daily dressing changes with nonadherent dressings or petrolatum gauze. However, parents must be cautioned that wound healing may take 4 to 8 weeks. Alternatively, these wounds can be skin grafted for accelerated healing. Full-thickness glabrous skin hypothenar grafts are preferred over split-thickness grafts, because the cosmetic result is superior and the return of sensibility is reportedly better.

Allen type II injuries involve the pulp and the nail bed. Similar to type I injuries, most superficial type II injuries can be conservatively treated.

Fig. 52-24 Allen zones of fingertip injury. (See the text and Table 52-2 for descriptions of and treatment options for each zone.)

Table 52-2 Treatment Options by Amputation Level	
Allen Type	Treatment Options
I	Conservative wound management Skin graft and/or allograft
II	Conservative wound management Skin graft and/or allograft Flap coverage Composite graft
III	Flap coverage Composite graft Closure of amputation
IV	Replantation Closure of amputation

Fig. 52-25 A, A thumb distal tip amputation from a meat slicer. B, A palmar V-Y advancement flap. C, Flap perfusion appeared compromised by excessive tension; therefore the tension was relieved by allograft interposition. D and E, The 3-month postoperative result.

Allen type III injuries involve the distal phalanx, and type IV injuries are amputations proximal to the lunula. Deeper type II to IV injuries can be treated with skin grafts, local flaps, composite grafts, or replantation. If the amputation is sharp and not crushed, the soft tissue can be cleaned, defatted to the dermis, and attached as a composite graft. Composite grafts have the best chance for success if they do not exceed 8 mm in length and are used in children younger than 3 years of age. The graft should be sutured with 4-0 or 5-0 plain gut sutures, secured with a bolster dressing, and immobilized. Even if a composite graft does not fully survive, it will serve as a biologic dressing while the deep tissues granulate. Alternatively, a digital tip amputation stump can be covered with a local advancement flap, cross-finger flap, thenar flap, kite flap,³⁵ neurovascular advancement flap,^{36,37} or neurovascular island flap,³⁸ particularly for exposed bone. The most commonly used local advancement flaps are the palmar (Atasoy) V-Y^{39,40} flaps. Lateral (Kutler) V-Y flaps⁴¹ have been described; however, we have been disappointed with the results in children and no longer use them. These flaps provide limited advancement; if they are placed under excessive tension, flap necrosis may result. We recommend advancement of the flaps and inset with sutures. The tourniquet is then deflated, and the digit is irrigated with warm saline solution. If a flap does not develop acceptable perfusion, then a small piece of full-thickness skin graft or allograft is used to relieve flap tension (Fig. 52-25).

AMPUTATION AND REVASCULARIZATION

Revascularized digits and amputations proximal to the distal phalanx are considered surgical emergencies and require prompt attention. It is general consensus that amputation of any body part in a child is an indication for replantation if the amputated segment is suitable for replanta-

Box 52-1 Goals of Replantation and Revascularization

Restoration of hand function and joint mobility
Recovery of sensation
Minimization of pain
Optimization of final cosmesis

tion and the patient has no concomitant life-threatening injuries.^{42,43} The goals of replantation and revascularization are listed in Box 52-1.

Absolute contraindications to replantation include concomitant life-threatening injuries and underlying medical conditions that preclude undergoing a long operation. Relative contraindications for pediatric replantation include severe crush injuries, multilevel amputations, the patient's mental instability, and prolonged ischemia time. Because of cellular death and reperfusion injury, it is generally recommended that replantation not be performed when the warm ischemia time is longer than 6 hours for amputations proximal to the carpus and longer than 12 hours for the digits.⁴⁴ However, preservation of the amputated part at 4° C will provide more time to perform the replantation safely (12 hours for amputations proximal to the carpus and 24 hours for digits). This rule is particularly applicable for digits that do not contain muscle and that have been successfully replanted after 94 hours of cold ischemia.⁴⁵

Patient Evaluation

The amputated part is collected and appropriately packaged for transport with the patient to a replantation center. The amputated part is best preserved by wrapping it in gauze moistened with saline solution, placing this in a watertight plastic bag, and placing the plastic bag in a cooler filled with ice.⁴⁶ The amputated part should not be immersed in fluid and should not directly contact ice. The patient should be kept well hydrated, warm, and given analgesics for pain relief. In most cases, bleeding from the proximal stump can be controlled with direct pressure without a tourniquet. Clamping of vessels is unnecessary and should be avoided. On arrival at the replantation center, the patient and amputated part are examined, appropriate antibiotic and tetanus prophylaxis given, and radiographs of the stump and amputated parts obtained. Then a frank discussion with the child's family is of paramount importance to explain the predicted morbidity of replantation/revascularization, the prognosis for replant survival, the potential need for reoperation, and the anticipated functional outcome. We do not guarantee replant success and always discuss the possibility of completion amputation. Furthermore, we have found that allowing the child and parents to see the injury fosters better understanding of the extent of damage, improves overall rapport, and fosters acceptance of the final result.

Mechanism of Injury

The mechanism of injury significantly affects the potential for a successful surgical outcome. Guillotine-type amputations have a relatively small zone of injury and carry favorable results.⁴⁷ In contrast, degloving and avulsion-type injuries, at first sight, do not appear to have large zones of injury; however, closer inspection under an operating microscope inevitably reveals significant damage to the neurovascular structures.⁴⁸ Avulsion-type injuries are often identified by nerves hanging from the distal amputated stump and tendons that have avulsed from proximal muscle

Fig. 52-26 **A**, A hand amputation showing tendon avulsions at the myotendinous junction with a 23 cm median nerve (*MN*) and 25 cm radial sensory nerve (*RSN*) avulsion. This hand was not replanted. **B**, An avulsion-type thumb amputation with a dangling digital nerve (*arrow*).

Fig. 52-27 A 10-year-old boy's thumb was amputated in a log-splitter accident. The palmar thumb is shown, with a palmar flap sutured back to expose the neurovascular structures. The amputated segment is stabilized on a sterile tongue blade. Before osteosynthesis, a forearm vein graft (*arrow*) is anastomosed.

bellies (Fig. 52-26). Crush injuries also carry a poor prognosis and have a large zone of injury. To help improve survival, aggressive debridement and vein grafting well out of the zone of injury are necessary.

Surgical Sequence

If possible, replantation should be performed using a two-team surgical approach. One team can take the amputated segment to the operating room (preferably) while the anesthesia team performs its workup. The part should be cleaned and debrided of nonviable tissues. In digital amputations, midlateral incisions are preferred for broad exposure of the vital structures. The digit can be sutured to a sterile tongue blade to serve as a stable platform for dissection (Fig. 52-27). Under an operating microscope the digital arteries, nerves, and dorsal veins are prepared for microsurgical anastomosis. We have found that tagging the arteries and veins with microhemoclips and the nerves with minihemoclips helps to readily identify these structures, particularly in a bloody field later in the operation. The tendons are tagged with sutures for future reference.

Before the induction of general anesthesia, a regional long-acting anesthetic block is given. Instead, preferably, an indwelling axillary catheter is placed for postoperative analgesia and vasodilation therapy. All bony prominences are padded, a Foley catheter is inserted, and warming

Box 52-2 Operative Sequence for Digital and Hand Replantation

1. Vessels, nerves, and tendons are identified and tagged.
2. Nonviable tissues are debrided.
3. The bone is shortened.
4. A stable bony fixation is obtained.
5. Tendons are repaired.
6. Nerves are repaired.
7. Readily identifiable veins are anastomosed; otherwise, arterial anastomosis is performed first.
8. The artery is anastomosed.
9. Skin coverage is completed.

blankets are used. At the outset of the operation, before exsanguination and tourniquet elevation, we routinely mark the course of the forearm veins in case vein grafts are later required. The typical operative sequence for digital and hand replantation is described in Box 52-2.

Several points deserve emphasis. Although its importance is often overlooked, obtaining rigid skeletal fixation allows early mobilization; thus it potentially facilitates superior postoperative range of motion. We have found that a 90-90 interosseous wire fixation technique provides rigid internal fixation and allows more aggressive postoperative therapy.⁴⁹ Another portion of the operation that is frequently performed in haste is the flexor tendon repair. Although the initial success of replantation and revascularization is judged by vascular patency, the ultimate result is related to the amount of active range of motion that is regained.⁵⁰ Therefore meticulous atraumatic technique is required for flexor tendon repair. We advocate using a 6-0 Prolene epitendinous suture, followed by a 4-0 nylon modified Kessler, and last a 4-0 nylon horizontal mattress suture.⁵⁰ The vascular repair deserves singular consideration. Under an operating microscope with high-power magnification (30×), the arteries and veins require careful inspection for intimal injury. Serial sectioning should be performed until there is no evidence of intimal damage. The vascular anastomosis should be tension free, and interposition-vein grafting should be readily performed to alleviate undue tension. We think that (if possible) at least two venous anastomoses should be performed (Fig. 52-28, *A*). The final step of this lengthy and delicate microsurgical operation is the skin closure. Inexperienced surgeons have a tendency to place excessive sutures when closing the wound. However, a tight closure leads to failure as the tissues swell and the thin-walled veins become compressed. The tissues need to be approximated loosely, and unmeshed skin grafts or allografts should be used liberally (Fig. 52-28, *B* and *C*). The use and mode of anticoagulants are controversial and the subject of debate. We give rectal aspirin just before the microvascular anastomosis and prescribe daily aspirin for 6 weeks. However, if the injury involves a significant crush component, in addition to aspirin, subtherapeutic intravenous heparin therapy is begun during the vascular anastomosis and is continued for 6 days.

In children, most amputations (unless the segment is severely damaged) should be replanted because of high overall rates of success,^{43,51,52} satisfactory return of sensation,⁵³ good total, active range of motion, and average bone growth of 93% compared with that of the uninjured side.^{53,54}

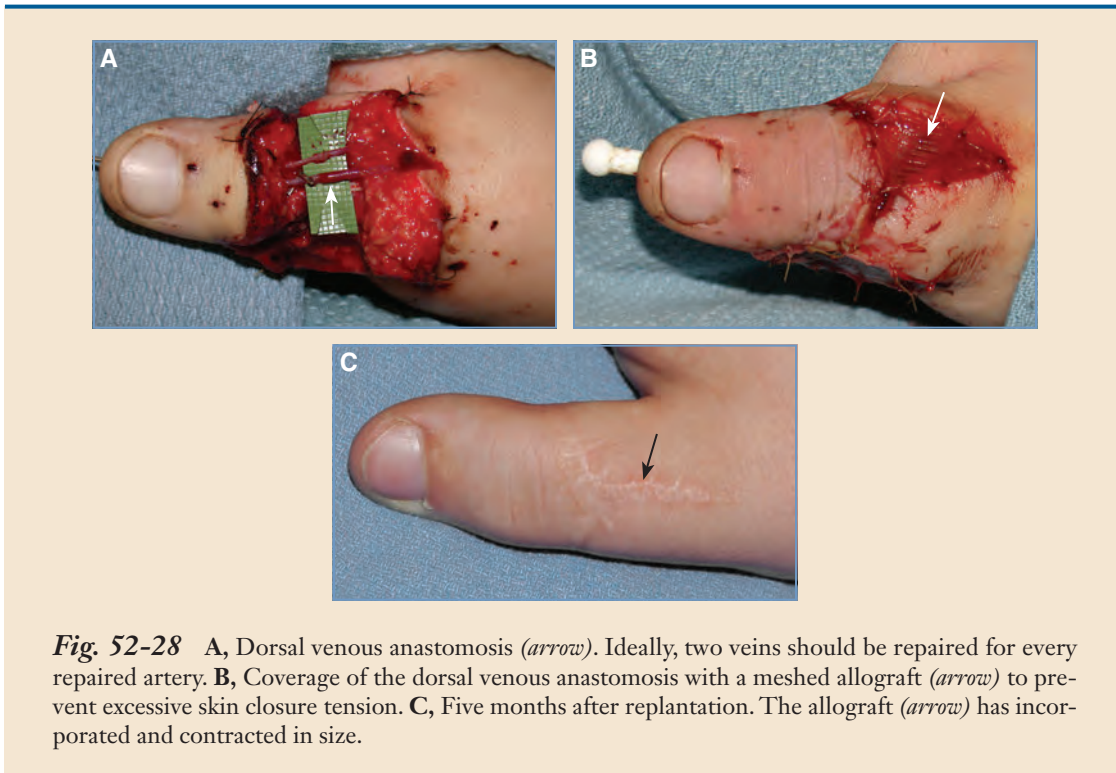

Fig. 52-28 A, Dorsal venous anastomosis (*arrow*). Ideally, two veins should be repaired for every repaired artery. B, Coverage of the dorsal venous anastomosis with a meshed allograft (*arrow*) to prevent excessive skin closure tension. C, Five months after replantation. The allograft (*arrow*) has incorporated and contracted in size.

The superior regenerative capacity of children's nerves and soft tissues, along with the potentially favorable psychological ramifications of improved cosmesis, makes this technically demanding operation most gratifying.

ACUTE NERVE INJURIES

The hand functions as a receptor for pain, texture, and temperature and can provide a “seeing” function to discern the shapes of objects when the eyes are not used. Alterations in hand sensitivity will affect these functions, thus affecting the ability to perceive and manipulate the surrounding environment.

In children, upper extremity nerve injuries are caused mainly by laceration from sharp objects, such as broken glass, and to a lesser extent, by fractures (supracondylar humerus).⁵⁵ Neurologic and motor examinations are key factors in determining the presence and extent of nerve damage. However, these examinations can be daunting in younger children and in those who are painful and frightened. The neurologic examination should begin on the uninjured extremity to gain the patient's trust and to allow the patient to more clearly understand the examination process. The examination begins by subjectively examining the distal sensation to light touch using a cotton-tip applicator. A more sensitive method of assessing for acute nerve injuries is the moving two-point discrimination test, which objectively evaluates the quantity of innervated sensory receptors.^{56,57}

Fig. 52-29 An evaluation of two-point discrimination. **A**, A bent paper clip method. **B**, Using a Disk-Criminator.

The simplest method for performing this test is to use a bent paper clip⁵⁸; however, more reliable instruments are available⁵⁹ (Fig. 52-29). In infants and children with undeveloped or unreliable communication skills, the water immersion test can be useful to identify nerve injuries.⁶⁰ The hand is immersed in room-temperature water for 10 minutes. Sensate skin will wrinkle and “prune,” whereas insensate skin will not.

Classification of Nerve Injuries

When discussing nerve injuries, it is useful to classify injuries as a prognostic indicator of functional outcome. In 1943 Seddon⁶¹ proposed a classification system that is widely used today; it is based on the disrupted portion of the peripheral nerve’s internal structure. In 1968 Sunderland⁶² expanded on the Seddon classification system. This modified classification gave more emphasis to the injured fascicular layer.

Sunderland’s “first-degree injury” corresponds with Seddon’s “neuropraxia” and is a minimally demyelinating injury resulting in a temporary conduction block. Complete recovery can be expected in days to months. Sunderland’s “second-degree injury” is Seddon’s “axonotmesis,” involving Wallerian degeneration of the distal nerve. Because the endoneurial layer is intact, complete return of nerve function can be expected in a matter of months. Sunderland’s “third-degree injury” corresponds with Seddon’s “neurotmesis.” The endoneurium is affected and scars with this injury pattern; therefore recovery is mildly to moderately reduced. A fourth-degree injury is the more severe form of axonotmesis, and the endoneurium and perineurium are involved. Scarring of these layers can be significant, resulting in neuroma in continuity and moderate reduction of nerve function. A fifth-degree injury corresponds with neurotmesis. The peripheral nerve is completely severed, and no return of function is possible unless the nerve ends are surgically coapted.⁶⁰ Mackinnon and colleagues^{63,64} have described a sixth-degree injury—a mixed combination of various degrees of nerve injury.

Timing of Nerve Repair

Sharp nerve injuries should be explored and repaired immediately when possible. The greatest chance for an uncomplicated primary repair is before inflammation, scarring, and retraction of the nerve stumps has occurred. Delayed repairs have a higher chance of requiring secondary nerve

reconstruction procedures to span a nerve gap, for example, using nerve tubes, vein conduits, decellularized allograft, and autograft. Nerves that have been avulsed or crushed and those resulting from a blast mechanism of injury sometimes demarcate further over time. Some advocate for delayed debridement and reconstruction of the ensuing gap. However, we tend to perform the earliest possible debridement and repair/reconstruction possible within the context of the injury and other possible needs, such as vascular reconstruction, bony stabilization, contamination, tissue viability, and soft tissue reconstruction.

Once a nerve injury is diagnosed, the patient is taken for exploration and operative repair. A nerve repair performed within 24 hours of injury is called a *primary repair*. A repair done in the first week is called a *delayed primary repair*, and those carried out after 7 to 14 days are called *secondary repairs*. If conditions are optimal, nerve repair should be performed as soon as reasonably possible. In our experience, repairs within the first 24 hours are technically simpler, and primary and delayed primary repairs usually have the most favorable results.

Management

Optimal conditions for nerve repair include a sharply transected nerve that has minimal crush and avulsion components. The vascularized soft tissue coverage should be sufficient and the wound bed free of contamination. Indications for nonoperative management or delayed nerve repair include poor general patient condition, extensive soft tissue damage (Fig. 52-30), gross wound contamination, and extensive nerve damage for which tendon transfers will more rapidly restore function.

Several techniques are available for repairing injured peripheral nerves. Despite the controversy over which is the best technique,⁶⁵⁻⁶⁷ certain time-tested principles should be adhered to,^{68,69} including the following:

1. Motor and sensory function are assessed preoperatively.
2. Meticulous microsurgical technique is performed.
3. The repair is tension free.
4. An interposition nerve graft is used when tension-free repair is not possible.
5. If clinical conditions allow, a primary repair is performed.
6. The repair is delayed for 21 days if conditions are not optimal for primary repair.
7. Early, protected range of motion is initiated.
8. Occupational therapy is essential for sensory and motor reeducation.

Fig. 52-30 This patient was involved in a rollover motor vehicle collision. The wound had extensive soft tissue damage, gross contamination, and segmental loss of the ulnar artery and nerve (*arrows*). The patient was managed with multiple debridements and soft tissue coverage, followed by delayed nerve graft reconstruction.

Techniques

End-to-end techniques are the preferred methods of nerve coaptation. Under an operating microscope, the nerve ends are serially sectioned until healthy, neuroma-free fascicles are encountered. The nerve is mobilized proximally and distally for a few centimeters to provide a tension-free repair. We consider tension to be appropriate when a single 8-0 or 9-0 nylon epineurial suture is capable of holding the nerve ends in approximation without pulling through. If the tension of the repair is deemed excessive, gentle joint-positioning maneuvers or nerve transposition can be performed. These maneuvers do not provide significant nerve stump advancement and are performed more to protect the repair itself if it is suspected of being under tension. If these maneuvers prove inadequate, the threshold for nerve grafting should be low.

An epineurial repair is considered the standard with which other repair techniques are compared. The fascicles are partially aligned using external topography (such as the longitudinal epineurial blood vessels) as a guide, and only the epineurium receives suture. This is a relatively fast technique that limits intraneurial trauma and is thought to have minimal foreign body reaction. Digital nerves receive two to three sutures and larger nerves receive eight to ten sutures of 9-0 nylon (Fig. 52-31), although the use of fibrin-based tissue glue can significantly reduce the number of nylon sutures needed. This technique is best suited for pure motor or sensory nerves and those with significant topographic crossover.

A group fascicular repair is used for larger nerves without topographic crossover, such as the distal median and ulnar nerves. This technique potentially improves repair accuracy by coapting matching fascicular groups with interfascicular perineurial suture. It is useful when performing cable grafts (Fig. 52-32).

A fascicular repair is a fairly uncommon technique that is used if individual fascicles are easily isolated. Each fascicle is repaired individually, providing more precise coaptation. The main disadvantages are that it is time consuming, the significant suture foreign body can result in intraneurial scarring, and tension in the repair needs to be minimal. This technique is appropriate for repairing digital nerves distal to the trifurcation.

If tension on a nerve repair cannot be completely relieved by conservative means (for example, if the nerve gap exceeds 2 cm, and nerve mobilization and conservative joint positioning maneuvers are inadequate), then nerve reconstruction grafting should be performed. For short gaps, nerve tubes may suffice. The exact length of a nerve gap that will be well served by a nerve tube is not known but in some centers is up to 2 cm. We have much more limited indications for nerve tubes and will not typically use them for gaps larger than 5 to 10 mm. Instead, we opt for nerve grafting. Excellent sources for nerve grafts include the antebrachial cutaneous nerves, the sural nerve, and the posterior interosseous nerve for digital nerve repairs. The nerve grafts are interposed in the defect, and a fascicular repair is performed. The results of nerve grafting are better than repairs performed under tension. Alternatives to nerve grafting include processed nerve allografts⁷⁰ and nerve tubes or conduits made from varying materials, such as autologous vein,^{71,72} collagen, or polyglycolic acid⁷³; these have shown promising results in small defects.⁷⁴

Postoperatively, the patient's hand is immobilized for about 3 weeks, with only conservative joint flexion or extension maneuvers. Beginning on postoperative day 7, and on a weekly basis thereafter, the joint is slowly and incrementally brought to neutral position. Nerve regeneration

halts for the first month after repair and resumes at a rate of 1 mm per day. The progression of regenerating nerves can be followed by an advancing Tinel sign. If no advancement occurs by 3 to 6 months, the repaired nerve should be reevaluated with nerve conduction studies or reexplored.

MUTILATING HAND INJURIES

A mutilated hand presents a significant challenge and is best cared for by hand surgeons proficient in reconstructive surgery and microsurgery. Caring for a child with mutilating hand injuries poses particular challenges with regard to more delicate anatomic structures, such as smaller-caliber vessels and tendons. The injuries may be less amenable to replantation and revascularization, because the mechanism of injury tends to be from meat grinders, saws, illegal fireworks,⁷⁵ and lawnmowers⁷⁶ (Fig. 52-33). To further complicate matters, parents often transfer their severe sense of guilt for not appropriately supervising their child to the health care team by being overly critical of the child's medical care or by becoming overly involved.⁷⁷ Despite these challenges, outcomes tend to be more favorable than in adults. Children inherently heal better and regain superior sensation with less long-term stiffness.

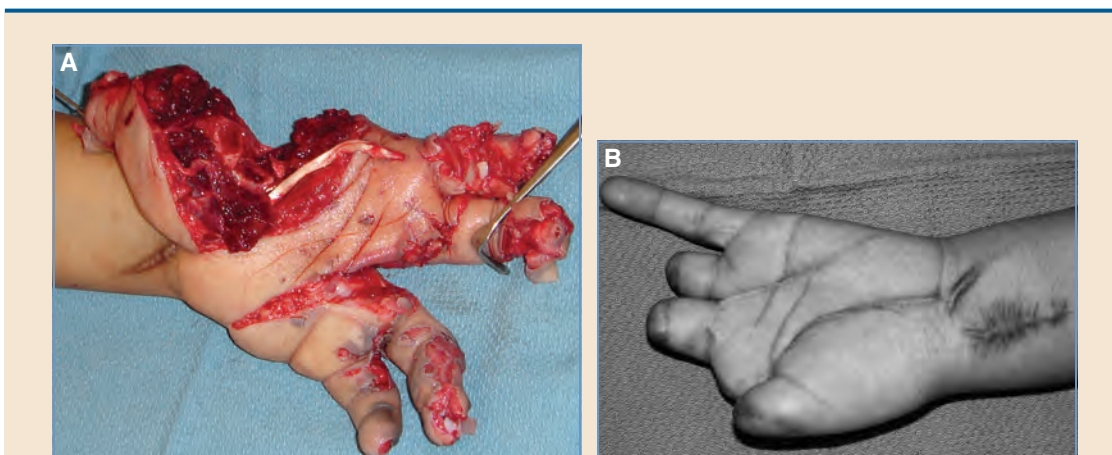

Fig. 52-33 A, A mutilating hand injury caused by fireworks. Revascularization, nerve repair, and finger amputations were required. B, The 4-month postoperative result.

The cornerstone of management of mutilating hand injuries involves early operative exploration, irrigation, and meticulous debridement of devitalized tissues. Care is required to prevent injury to vital structures such as tendons, nerves, and vessels during the debridement. We have found that copious pulse-lavage irrigation using saline solution impregnated with antibiotics aids in the safe debridement of foreign material and bacteria.

Damaged tissues are generally repaired in the same sequence as that used for a replantation, beginning with the larger, stabilizing structures such as bone osteosynthesis to maintain length, followed by tendon repairs.⁷⁶ Next, the neurovascular structures are repaired and the soft tissue coverage provided. After the arterial repair, the veins are allowed to bleed for several minutes before venous return is confirmed and before venous anastomosis to prevent the introduction of muscle breakdown products and proinflammatory mediators into the systemic circulation.

Although adequate soft tissue coverage is crucial for functional recovery after mutilating hand traumas, this coverage is often difficult to obtain. Flap coverage may be required; this should be delayed until the soft tissues are viable and infection free. To reach this stage, multiple trips to the operating room may be required for irrigation and debridement. In the interim, we have found negative pressure wound therapy to be an invaluable aid for decreasing tissue edema and for maintaining a moist environment over exposed tendons. Definitive soft tissue coverage depends on the defect and should be individualized for the patient. Wound coverage can be as simple as skin grafting or as complex as pedicled flaps and microvascular transfer. An ideal flap should provide vascularity and be thin and pliable, allowing appropriate joint movement, tendon excursion, and the potential for reelevation for revision surgery, including tenolysis/tendon reconstruction, delayed bone grafting, and hardware removal.

KEY POINTS

- Upper extremity injuries, particularly those of the hand, are common in toddlers as they explore their environment and in older children and teens who engage in sports.
- Differences in anatomy, growth potential, and rehabilitation outcome require adjustments to the treatment protocols used in adults.
- Closed reduction of Salter-Harris type II fractures is usually successful, but rotational deformities with scissoring cannot be left untreated.
- Flexor tendon repairs are performed much like those in adults except on a smaller scale, and postoperative protective immobilization is required in young children.
- Reconstruction requiring tenolysis or tendon grafting should be reserved for more cooperative older children and teens.
- Fingertip injuries are very common in toddlers, and careful, meticulous repair of bone and soft tissue can provide excellent results.
- Replantation of amputated parts is usually attempted in children as long as the part is suitable for replantation and prolonged surgery is not contraindicated.

ACKNOWLEDGMENT

We wish to thank Delbar Azari, MS, for her illustrations and photographs.

Management of Obstetrical Brachial Plexus Palsy

Kristen M. Davidge • Jeffrey R. Marcus • Howard M. Clarke

Obstetrical brachial plexus palsy is a traction neural injury that occurs during the birth process. As with all closed peripheral nerve injuries, the spectrum of severity is wide, and the degree of severity is the key determinant of prognosis and the need for intervention. Unlike single peripheral nerve injuries, the challenge of predicting severity and outcome for the brachial plexus is far greater because of the intricate pattern of this incompletely understood group of nerves. Opinions differ for managing obstetrical lesions of the brachial plexus in newborns. Microsurgical treatment in this area is a developing field. Surgeons engaged in early efforts to improve functional outcomes for infants with this potentially lifelong impairment quickly recognized the need to establish appropriate surgical criteria. Determining surgical indications is the most important and the most difficult step in caring for patients and families attempting to cope with the physical and emotional impacts of this condition. The factor most responsible for the disagreement among experts is the relatively incomplete understanding of the natural history of brachial plexus palsy. In this chapter we discuss the anatomy of the brachial plexus, the initial approach to patients with brachial plexus palsy, the natural history of the condition, the primary surgical treatment, and the expectations for outcome.

ANATOMY OF THE BRACHIAL PLEXUS

The anatomy of the brachial plexus is shown in Fig. 53-1. In most configurations the brachial plexus is formed from spinal roots C5-T1. *Prefixed* describes a plexus extending from C4, and *postfixed* describes a plexus extending to T2. As the roots emerge from their respective foramina, a characteristic branch pattern develops, which uses the following nomenclature: roots, trunks,

divisions, cords, terminal branches, and peripheral nerves. The trunks form as the roots converge between the anterior and middle scalene muscles. The upper trunk forms from C5 and C6, the middle trunk from C7, and the lower trunk from C8 and T1. Anterior and posterior divisions are formed for each trunk as they pass beneath the clavicle. Beneath the pectoralis minor the divisions converge with one another to form three cords: (1) the lateral, (2) the medial, and (3) the posterior cords, named with respect to their position relative to the axillary artery. The lateral cord is formed from the anterior divisions of the upper trunks, the medial cord is the continuation of the anterior division of the lower trunk, and all three posterior divisions form the posterior cord. Therefore the posterior cord contains input from all five of the spinal roots. Innervation of proximal muscle groups (that is, the shoulder girdle) originates from the root, trunk, and cord levels, whereas innervation of the upper and lower arm comes from terminal branches and ultimately from peripheral nerves more distally. The median nerve forms from contributions of the lateral and medial cords. The ulnar nerve and myocutaneous nerve are terminal branches of the medial and lateral cords, respectively. The radial and axillary nerves are terminal branches of the posterior cord.

Fig. 53-2 Injury patterns to the spinal nerves. A preganglionic tear of the spinal nerve from the spinal cord is called an *avulsion*. Postganglionic tears are known as *ruptures*. A complete rupture is demonstrated by loss of continuity of the nerve. Also possible is an intraneural rupture of the fascicles in which some fascicles remain intact but others are dissociated within the epineurial envelope.

The level of injury within the plexus (from proximal to distal) can be determined to some extent from physical findings. A review of the brachial plexus anatomy—particularly the proximal branches—clarifies the location. For example, the presence of Horner syndrome indicates disruption of C8-T1 proximal to the sympathetic rami communicantes (a root avulsion). Scapular winging indicates a relatively proximal injury, because the long thoracic nerve supplying the serratus anterior originates at the root level distal to the foramina from C5, C6, and C7 contributions. The physical findings related to the level of injury are discussed in more detail in the discussion of physical examination.

Nerve injury patterns merit specific comment (Fig. 53-2). Injury of a single spinal nerve can occur at any level from the spinal cord origin to the terminal branches. The most proximal injury is a preganglionic tear of the spinal nerve rootlets from the cord, called *root avulsion*. Root repair, that is, replantation of avulsed rootlets, is currently not technically feasible. A postganglionic tear of the spinal nerve is a *rupture*. Whether the two free ends are separated, or whether they remain in continuity through only scar tissue, the axons are severed. Here, the proximal stumps are potential sources of viable axons for reconstruction, and the distal ends may serve as graft recipients. Intraneural rupture of fascicles results in a mixed injury; some fascicles remain intact and others are disrupted within the epineurial envelope. The result—neuroma in continuity—is the most frequent finding at surgery for brachial plexus reconstruction. Obstetrical injuries to the brachial plexus can result in variable combinations of all of these injuries.

EPIDEMIOLOGY

In modern obstetrical practice, the incidence of obstetrical brachial plexus injury is estimated at 0.5 to 2 per 1000 births.^{1,2} Included in this estimate are those who progress quickly to complete recovery and those who improve slowly and incompletely. In reported series, the rate of complete, spontaneous recovery varies widely (30% to 95%).³⁻⁷ Lower reported rates reflect, in part, preselection; those who recover quickly and completely often are not referred to specialists and may be excluded from analyses. The definition of *recovery* is inconsistent. Although many infants with plexopathy recover with minor or no residual functional deficits, some children do not regain sufficient limb function and develop functional limitations, bony deformities, and joint contractures. Imbalanced shoulder girdle musculature resulting from incomplete recovery can lead to subluxation of the shoulder and deformation of the glenoid.^{8,9} Bony deformities and contracture can occur even in cases with reported complete neurologic recovery.¹⁰ Birch^{11,12} stated that palliative procedures for secondary deformities are deeply unsatisfactory, and the results of myotendinous transfers in obstetrical palsy are far inferior to those that follow good nerve regeneration. The challenge of statistical prognostication is to identify children most likely to benefit from exploration and reconstruction of the plexus.

HISTORY

At presentation, a detailed history should be taken that addresses maternal factors, the prenatal course, events of the delivery, and the postnatal course. Fig. 53-3 presents an example of the historical data reference used at our institution. For the purposes of data collection, historical items in this format have been separated into two categories: maternal factors and child factors. Maternal factors include data pertaining to the prenatal history, such as maternal diabetes, preeclampsia, duration of labor, and previous obstetrical history. The natal history described by the parents includes delivery presentation, the use of instrument assistance, and shoulder dystocia. Child factors include gestational age, weight, and complications such as respiratory complications, fractures, diaphragm paralysis, and shoulder subluxation.

Historical data are documented for the purposes of population study. Some centers that receive a larger number of referrals have an internal database that allows analysis and reporting of relatively large series, which has led to our current, yet still incomplete, understanding of the disease process. Participation of all centers, particularly smaller ones, in web-based, multicenter data collection programs may be helpful. One example is the multicenter database sponsored by Children's Hospital of Boston. This database compiles historical information and serial examination data. With regard to history, attention is focused on factors that have reported statistical associations with obstetrical brachial plexus injury. The factors of interest are those with suspected causal relationships to the injury, those that might indicate a high level of energy at the time of injury, and those that may suggest the anatomic level of injury.

Several associations have been consistent in the literature. The average birth weight of affected infants is reported to be 500 to 1000 g heavier than that of unaffected infants.¹ The reported association of maternal diabetes with obstetrical lesions is probably a result of its effect on birth weight. After the first pregnancy, birth weights tend to increase with each successive pregnancy. Fetal macrosomia is another condition that, although cited separately, is associated with higher average birth weight.¹³ Generally, these conditions share the same potential delivery-related difficulty, that is, cephalopelvic disproportion.^{14,15} Shoulder dystocia is perhaps the most common association, and the mechanism of vertex brachial plexus injury is most easily understood in this context. It is generally accepted that injury to the brachial plexus is a result of lateral displacement of an infant's head away from the shoulder during the last phase of delivery.^{1,14,16,17} Other

reported associations include brachial plexus injury in previous pregnancies and the use of vacuum or forceps assistance during delivery.

The incidence of concurrent delivery-related injuries, such as fractures or dislocations, needs to be determined. Some think that such injuries provide meaningful clinical suggestions regarding the applied energy at the time of injury. For example, a fracture of the humerus may indicate significant applied energy. Humeral fractures may also be associated with pseudoparalysis, in which neurologic impairment occurs as a result of direct impingement of the plexus by the fracture itself. Clavicular fractures have been associated with obstetrical plexus injury,⁶ but some suggest that it may actually be protective to a certain degree,¹⁷ allowing downward rotation of the shoulder-scapular complex during dystocia. Shoulder dislocations can occur with or without injury to the brachial plexus. The literature does not provide a statistical association of prognosis with the incidence of humeral and clavicular fractures.¹⁸

Brachial plexus injuries are most frequently reported after vertex deliveries, but they have also been reported with breech deliveries and cesarean sections. Metaizeau et al¹⁷ investigated the effects of traction on the brachial plexus in stillborn infants. Immobilizing the shoulder and applying lateral traction to the head demonstrated force requirements and patterns of injury. Epineurial ruptures occurred at a lower force level than complete ruptures. Ruptures were more common in the upper roots and avulsions in the lower roots.¹⁶ The findings of Metaizeau et al¹⁷ coincide with clinical observations and injury patterns in vertex deliveries with plexopathy. In breech deliveries with plexopathy, a lower-than-normal birth weight is more common, whereas the converse is true with vertex deliveries. The characteristic injury pattern tends to be more severe in breech deliveries, particularly at the upper roots. Avulsions of C5 and C6 are frequently seen.¹⁹⁻²¹ Brachial plexus injuries with breech presentations have been most clearly documented by European groups. Recently Al-Qattan²² reported on a series of patients with obstetrical plexopathy in association with breech delivery in Saudi Arabia, which echoes the findings noted previously. Relatively fewer cases of breech-related plexopathy are seen in North America, perhaps because of a greater tendency to perform a cesarean section under such circumstances. However, investigators have noted an approximately 1.5% incidence of brachial plexopathy after cesarean section.^{5,16,23} Clinical evidence of brachial plexus trauma with characteristic neuroma formation is described for reported postcesarean patients who proceed to exploratory operations. An urgent cesarean section may follow a difficult initial attempt at vaginal delivery. In such cases, the same potential injury mechanisms resulting from vertex vaginal delivery may occur. The perceived inconsistency of injury after cesarean sections with the commonly accepted mechanism for vertex-related plexopathy has prompted some to suggest the possibility of intrauterine injury to the plexus or congenital malformation. This hypothesis is not yet supported by conclusive data.

PHYSICAL EXAMINATION AND MOTOR ASSESSMENT

A thorough examination should be conducted, with the following goals:

- Determining the presenting functional severity
- Identifying other traumatic injuries or complicating factors
- Querying for possible confounding diagnoses

Physical Examination

The head, neck, and shoulders are examined. The position of the head is assessed for favored laterality, which could indicate the presence of either primary or secondary torticollis. Primary (true) torticollis can be seen immediately after birth in infants with a brachial plexus injury and after an uneventful delivery in infants without brachial plexopathy. However, children with

Fig. 53-4 The typical posture of an infant with right upper trunk palsy. The shoulder is held in adduction with the elbow straight. The wrist, fingers, and thumb are flexed. This is sometimes referred to as the *waiter's tip position*.

brachial plexus injury tend to look away from the affected side despite the absence of true torticollis. Parents tend to nurse with the child's affected arm up. Unless the condition is diagnosed and treated with physical therapy, sternocleidomastoid shortening and secondary torticollis can gradually develop.^{16,23}

The upper extremities are carefully examined with the child at rest. After a brachial plexus injury, one of a few distinct patterns is followed. The first is characteristic of upper plexus palsy (Erb palsy), in which deficits are primarily at the shoulder and elbow. The level of involvement in this injury is C5-6, and possibly C7. The resting position, which favors the more richly innervated or least affected muscle groups, is characterized in upper root palsy by adduction and internal rotation of the shoulder, extension of the elbow, pronation of the forearm, and flexion of the wrist and fingers. This position is sometimes referred to as the *waiter's tip position* (Fig. 53-4). A second common injury pattern is total plexus palsy, which is characterized by complete atonia of the upper extremity (C5-8 and possibly T1). These infants often give little to no attention to the affected extremity. Klumpke paralysis, or lower plexus palsy, refers to isolated involvement of C8 and T1, and it is generally not seen as a manifestation of obstetrical palsy.²⁴ The pathology of intermediate plexus palsy, primarily affecting C7 and sometimes C8 and T1, is well described.²⁵ However, it is generally not characterized by a unique or classic position at rest during the early period of evaluation. The appearance usually resembles that of upper or total plexus palsy, depending on the extent of involvement of the less injured roots. A final injury pattern, isolated C7 avulsion, is uncommon and presents primarily as a flexion deformity at the elbow.

The clavicles, humeri, and ribs are evaluated for fractures. The position and posture of the shoulders are evaluated for dislocation. The scapulas are difficult, if not impossible, to evaluate in infants. Asymmetry and winging in older children may suggest a proximal injury with impairment of the long thoracic nerve. The phrenic nerve is another proximally based branch, with contribution from C3-5.^{26,27} Breathing is carefully evaluated to determine involvement of the phrenic nerve. Symmetrical movement of the rib cage with coordinated abdominal movement should be seen. In our practice, all preoperative patients receive ultrasound imaging of the diaphragm. Postoperatively, in some cases, transient hemiparalysis of the diaphragm can result from traction during the course of dissection. If such a patient had a normal preoperative study, resolution is

probable with expectant management. In principle, a paralyzed hemidiaphragm may require plication to improve function; however, we have not encountered this situation. Finally, the pupils and eyes are examined for signs of Horner syndrome: ptosis, miosis, anhidrosis, and enophthalmos. These findings suggest a more proximal injury^{19,28,29}; specifically, they indicate disruption of T1 proximal to the sympathetic rami communicantes. Preganglionic sympathetic fibers arise from T1 (and often T2). Just after T1 exits its intervertebral foramen, the fibers branch from the spinal nerve to enter the sympathetic chain through the white rami communicantes. They subsequently travel to the superior cervical ganglion and synapse. From there, postganglionic fibers proceed along the carotid plexus to innervate the dilator pupillae muscle and levator palpebrae muscle. A T1 injury distal to the rami communicantes does not disrupt the sympathetic fibers; therefore it does not result in Horner syndrome.

Motor Assessment

Motor assessment is perhaps the most important component of a systematic examination. In neonates and infants, however, it is the most difficult. Accuracy and consistency require patience and experience and are important for decision-making for each patient and for systematic evaluation of global treatment plans. Assessment of motor function in older children and adults is more straightforward and involves the use of grading scales based on a level of demonstrable voluntary power. The British Medical Research Council’s familiar 0 through 5 grading scale is shown in Table 53-1.³⁰ Because infants cannot participate in testing that requires voluntary demonstration of full power, some investigators have sought to develop instruments based on range of motion rather than power. Such is the case for the muscle grading system of Gilbert and Tassin³¹ (Table 53-2), which considers the presence or absence of movement with and without the effect of gravity. The scale is simple, easy to apply, and widely recognized. However, because it must cover a wide range of ability within four possible grades (M0 to M3), its discriminatory capacity is limited. Furthermore, the scale has never been subjected to validation studies.

The Hospital for Sick Children’s Active Movement Scale is an eight-point assessment scale for active range of motion^{16,32} (Table 53-3). It was designed to be highly discriminatory, capturing subtle and significant changes in movement.^{16,23} Similar to the grading system of Gilbert and Tassin,³¹ it addresses range of motion in the presence and absence of gravity. Further, however, it quantifies the active range under each of these conditions. A number of guidelines have been

Table 53-1 British Medical Research Council’s Muscle Grading System	
Observation	Muscle Grade
No contraction	0
Flicker or trace of contraction	1
Active movement with gravity eliminated	2
Active movement against gravity	3
Active movement against gravity and resistance	4
Normal power	5

Table 53-3 Hospital for Sick Children's Active Movement Scale

Observation	Muscle Grade
Gravity Eliminated	
No contraction	0
Contraction, no motion	1
Motion $\leq \frac{1}{2}$ range	2
Motion $> \frac{1}{2}$ range	3
Full motion	4
Against Gravity	
Motion $\leq \frac{1}{2}$ range	5
Motion $> \frac{1}{2}$ range	6
Full motion	7

Data from Clarke HM, Curtis CG. An approach to obstetrical brachial plexus injuries. *Hand Clin* 11:563; discussion 580, 1995.

developed in an effort to instruct others in its use and to standardize application of the scale. For example, infants often demonstrate limited movement both with and without gravity effects. With the Active Movement Scale, infants cannot be scored against gravity unless they first achieve a score of 4, reflecting a full, active range without gravity. Gravity-eliminated movements are always assessed first to determine whether higher scores might subsequently be assigned. The scoring system is applied to the key movements of each potentially affected joint: shoulder flexion, abduction, adduction, internal and external rotation, elbow flexion and extension, pronation and supination of the forearm, wrist flexion and extension, finger flexion and extension, and thumb flexion and extension. Practical applications of the instrument have been described in detail in the literature^{16,23,32}; the specific guidelines and suggestions are essential to its consistency. Reliability studies of the Active Movement Scale have shown consistent intrarater reproducibility and interrater reliability among experienced and recently trained physiotherapists. Variability is a result of patient factors rather than rater factors.³²

Here is a final note on the motor examination: It is just as important for any grading scale to be reliable and discriminatory as it is to be applicable along the full range of a child's development.

	II	III	IV
ACTIVE ABDUCTION	 Inferior to 30°	 30° to 90°	 Superior to 90°
EXTERNAL ROTATION	 0°	 Inferior to 20°	 Superior to 20°
HAND TO NAPE OF NECK	 Impossible	 Difficult	 Easy
HAND TO BACK	 Impossible	 S1	 T12
HAND TO MOUTH	 Claron	 Small claron	

Fig. 53-5 Mallet’s classification system evaluates global movement of the extremity to identify functional or maladaptive patterns. It requires cooperation from the patient to perform voluntary movements on command.

A major advantage of scales such as the Active Movement Scale and Gilbert and Tassin’s muscle grading system³¹ is that they can be administered during infancy and repeatedly throughout development, including postoperatively. This allows consistent analysis of the patient and is a statistically sound means to study the natural history of the injury and postoperative results. In 1972 Mallet^{33,34} established a grading scale that addressed global movement of the extremity and functional adaptations³⁵ (Fig. 53-5). It is widely used and assesses the functional utility of the extremity by grading such composite movements as “hand to nape of neck.” Mallet’s classification^{33,34} is limited because directed, complex movements are not reliably provoked in infants, who often are first examined at 1 to 3 months of age. We strongly support consecutive application of the same test instrument during development for both clinical and analytic purposes; therefore we have not incorporated the Mallet classification into our routine clinical practice.

PROGNOSIS AND THE DECISION FOR SURGICAL EXPLORATION

Most investigators agree that children who will ultimately require surgery should be treated as early as possible to maximize the benefit of the intervention. The difficulty lies in accurately identifying these children early. There are two circumstances in which, given our current level

of understanding, the indications for surgery are quite clear early on. First, as Waters³⁶ indicated, normal neurologic function can be almost universally expected without surgery in patients who demonstrate recovery of neurologic function within 1 month after birth. His conclusions, which support the work of Eng et al,¹ Michelow et al,⁵ and Tassin,³⁷ were based on the first noted appearance of biceps function by 1 month in 8 of 66 patients who were followed for a minimum of 2 years. A large proportion of patients probably fall into this group. Although we would prefer to follow all patients, realistically many patients in this category may recover without ever proceeding to a specialist referral. At the opposite end of the spectrum, a poor, long-term functional result is expected if no intervention is undertaken for an infant who has total plexus palsy with signs of Horner syndrome and fails to improve over the first 3 months. Numerous investigators have stated that the presence of unequivocal Horner signs inevitably indicate a need for early exploration.^{16,28,29} In Waters' series,³⁶ 8 of 66 patients (12%) demonstrated recovery within 1 month; only 3 of 66 (5%) had total palsy with Horner syndrome. Thus nearly 80% of the patients in this tertiary referral-based series presented with injury severity between these extremes, indicating that additional data and selection criteria are necessary.

Surgery is indicated if evidence shows that the outcome after intervention is likely to result in better long-term function than that resulting from conservative management. To make this judgment, the natural history of the condition must be known along its full spectrum of severity. If predictors of poor outcome can be identified and used as surgical criteria, then a comparative outcome study could be conducted to evaluate treatment effects. The approach taken by Tassin³⁷ and Gilbert and Tassin³⁸ in 1984 focused on predicting shoulder outcome in 44 patients with obstetrical palsy. They observed that over a 5-year period, a "good shoulder" (Mallet class IV) was not obtained unless biceps and deltoid contraction began by the third month.^{37,38} They reported, "An average (class III) or bad (class II) shoulder developed if biceps or deltoid recovery began after the third month." Because of the perceived difficulty in evaluating deltoid function, the authors recommended the absence of elbow flexion alone at 3 months as the primary indication for surgical exploration. The absence of elbow flexion at 3 months has become the most widely accepted criterion for surgery in cases that fall between the two previously mentioned extremes (i.e., normal or no neurologic recovery).

Some think this criterion may result in a too-high false-positive rate and a surgical recommendation for some children who would otherwise recover satisfactorily with nonoperative treatment. In our study of the natural history, we reported the progressive changes in active movement over a 12-month period in 66 patients with obstetrical palsy.⁵ In this series, patients were evaluated repeatedly at 6-month intervals after birth using an earlier version of the Hospital for Sick Children Active Movement Scale. The cardinal movements at the shoulder, elbow, forearm, wrist, and hand were graded. At 12 months, patient outcomes were assessed according to the Narakas classification,³⁹ in which poor recovery was defined as elbow flexion of half or less of the normal range and shoulder abduction of less than half the normal range. For a functional range beyond these limits, recovery is considered to be good. We conducted an analysis to determine whether the recovery of any one motion or set of motions at 3 months could statistically predict poor recovery. Absent elbow flexion alone at 3 months incorrectly predicted a poor recovery 12.3% of the time. Using a composite score of elbow flexion plus elbow, wrist, thumb, and finger extension at 3 months, poor recovery was incorrectly predicted 5.2% of the time at a cutoff score of 3.5. Therefore we concluded that an additional 7.1% of children could be spared surgery and still be expected to achieve a good recovery if the more comprehensive score is used.

Waters³⁶ also investigated recovery of elbow flexion as an independent criterion for surgery. In his very elegant and careful study of 66 patients with obstetrical palsy, he evaluated recovery of biceps function monthly from birth to 6 months of age. The outcome was based on the Mallet global functional movement scale. Mallet scores were determined at each evaluation, and the minimum follow-up for all patients was 2 years. Waters found that patients who recovered biceps

function within 4 to 6 months after birth did not proceed to normal global function, unlike those who recovered biceps function within the first 3 months. For those who underwent surgery at 6 months because of biceps recovery failure, the outcome was better than for those who regained function at 5 months and did not undergo surgery. The findings further support the idea that the specific timing of recovery is an important prognostic variable, and that surgical outcome can surpass natural history in carefully selected patients. Therefore Waters concluded that, in addition to patients with total palsy who do not improve by 3 months, surgery should be offered to patients who do not recover biceps function by 5 months.

Strombeck et al² studied 247 patients, of whom 54% recovered function of the biceps within 3 months and later progressed to satisfactory function. They reported unchanging total plexus palsy at 3 months in 13% of patients and recommended surgery for all of them. Most of the remaining patients (33%) were observed for “late recovery,” which was defined as biceps recovery at the 6-month or 9-month evaluation. Those who did not regain biceps function at these later times were recommended for surgery. The authors found that late recovery occurred, and no significant difference was noted in outcome between the group that underwent surgery and the group that did not, except for improved shoulder movement in those with upper plexus lesions. The findings led the authors to reject the 3-month biceps recovery criteria altogether in favor of waiting for late recovery. Although we agree that a small number of patients regain biceps function after 3 months and proceed to satisfactory recovery, waiting for late recovery in all cases is not appropriate. In our natural history study, half of the patients with no elbow flexion at 3 months later developed good function, but the other half did not. The test score developed from this study was designed to identify patients with a statistical likelihood of poor recovery while limiting the number of incorrect predictions. Based on this information, an early surgical recommendation may have been given to some of the patients in the Strombeck study. Although the surgical patients in their study (those with more severe injury) had later operations, they still had functional recovery that was at least as good as the recovery of those who were observed (those with presumably less severe injury). A careful statistical approach to surgical indications, such as those of Waters³⁶ or Michelow et al,⁵ can limit low-yield interventions while maximizing the potential benefits of surgery by making early recommendations when appropriate.

The false-negative findings with the elbow flexion criteria of Tassin³⁷ and Gilbert and Tassin³⁸ at 3 months are a concern. In cases with a normal test result (flexion of the elbow), surgery would be deferred. A small percentage of children who meet such criteria at the 3-month interval may still have a poor recovery. Therefore assessments must continue to be carried out at 3-month intervals to ensure that children with early evidence of recovery progress satisfactorily.

In our practice, a test score is determined at the 3-month assessment based on the following statistical discriminators, which together were shown to limit the false prediction rate for poor recovery to only 5.3%: elbow flexion and elbow, wrist, finger, and thumb extension.⁵ Patients with a test score of greater than 3.5 are observed and continue physical therapy to maintain their range of motion. Active Movement Scale scores are assessed every 3 months. Some patients with upper trunk lesions who show good early recovery and have test scores greater than 3.5 may not develop adequate elbow flexion by the end of their first year and may have poor shoulder function. In these cases, surgical exploration is offered for patients who at 9 months of age demonstrate elbow flexion of less than grade 6 (less than half the range of motion against gravity). At this age children can better cooperate during evaluations of more complex functional movements; therefore elbow flexion is assessed with what we call the *cookie test*. The elbow is held in adduction at the trunk, a small cookie is placed in the child's hand, and the child is encouraged to bring it to his or her mouth. The child passes the test and is rejected as a surgical candidate only if he or she cannot take the cookie to the mouth by elbow flexion against gravity and with less than 45 degrees of neck flexion.^{16,32}

Surgery is recommended for patients who do not achieve a test score of 3.5 at the 3-month examination (capturing the most severe cases) and for patients who fail the cookie test at the 9-month interval (capturing the mildest cases that will benefit from surgery). For some children, surgery is offered at the 6-month interval if they initially demonstrated elbow flexion at the 3-month assessment but failed to progress. If they have not progressed since the first few months and the 3- and 6-month scores are similar, further improvement is unlikely. At 6 months, infants generally are not yet able to cooperate with the demands of the cookie test. Insufficient satisfactory progress in test scores between 3 and 6 months of age serves to identify intermediate cases. These children might have benefited from surgery at an earlier time.

Some infants pass the cookie test at 9 months of age but do not recover good shoulder function. We recently revised the Hospital for Sick Children algorithm for evaluation and management of infants with obstetrical brachial plexus palsy to include inadequate spontaneous recovery of shoulder function as a separate indication for a primary nerve operation at 9 months of age⁴⁰ (Fig. 53-6). This change in practice was based on a review of 17 patients who were offered

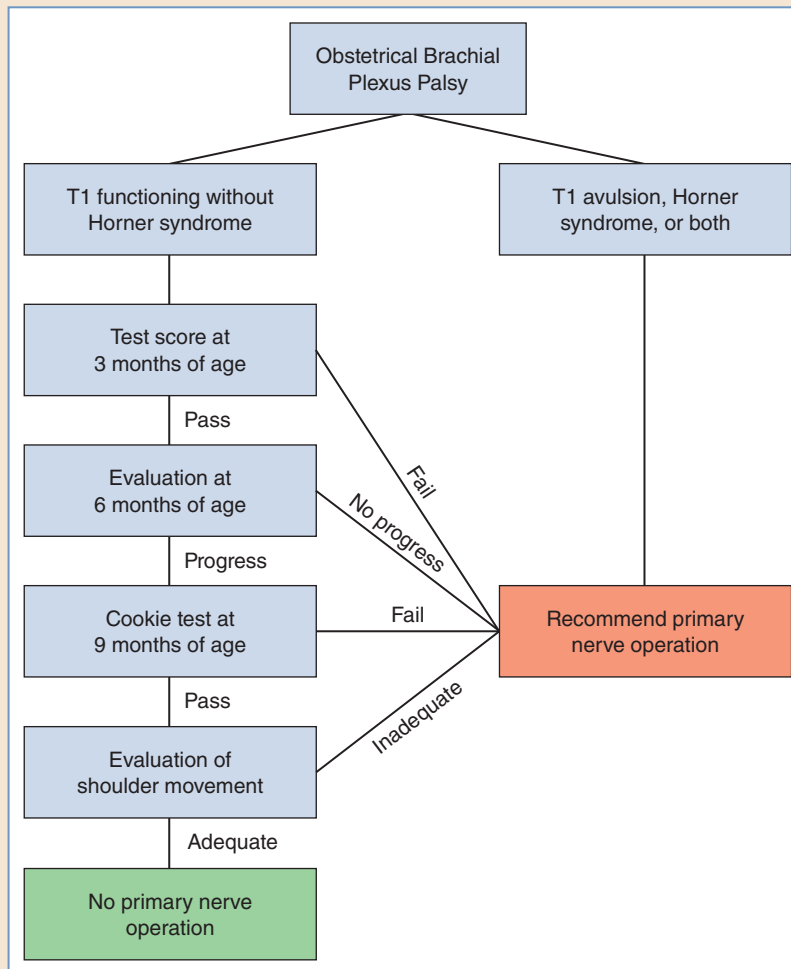

Fig. 53-6 A flow diagram of the extended indications for primary nerve surgery in obstetrical brachial plexus injury used in our center.

a primary nerve operation between 2004 and 2009 on the basis of poor shoulder function, despite adequate elbow flexion.³⁷ Sixteen of these patients had no active external rotation (Active Movement Scale score of 0), and, of more importance, all patients had sufficient passive range of motion to demonstrate poor active range. Of the 14 patients who underwent surgery, 11 patients had an isolated suprascapular to spinal accessory nerve transfer from an anterior approach for absent active external rotation. The other 3 patients underwent a neuroma excision and grafting of the upper trunk, or upper and middle trunk, because of poor active range in shoulder flexion and abduction. All patients in the operated group regained some active external rotation of the shoulder (Active Movement Scale scores ranging from 2 to 7), and they regained or surpassed their scores for other shoulder motions. By contrast, in the nonoperated group, 2 of 3 patients did not demonstrate further recovery in active external rotation, and it remained absent.

All appropriate patients should be offered surgical reconstruction of brachial plexus palsy lesions. For children most severely affected, this decision is made when they are 3 months of age; a failure of the test score, a positive Horner sign, or clinical evidence of a T1 avulsion is sufficient to indicate that surgical reconstruction should be offered. At the other end of the spectrum, a failed cookie test or poor shoulder function in children 9 months of age indicates some degree of early spontaneous recovery but failure to reach an adequate plateau that would suggest a good final outcome. Patients with an intermediate pattern are treated at an intermediate time interval.

The decision to perform surgical exploration of the brachial plexus in infants is not easily made. Challenging questions about management do not end at this point. Exploration of the brachial plexus is a technically elegant first stage of the operation, exposing and revealing the grossly apparent sequelae of a closed traction injury. Once the plexus is exposed, more challenges arise, including identifying root avulsions and managing neuroma-in-continuity lesions by neurolysis, neuroma resection and grafting, or neurotization.

SURGICAL APPROACH: EXPLORATION OF THE BRACHIAL PLEXUS

Positioning

The infant is placed in the supine position fully at the head of the bed and close to the lateral edge on the injured side (Fig. 53-7). This allows the surgeon and assistants to work from above, beside, and below the field. The entire upper extremity, upper chest, and neck are prepared in the field. The arm is placed in a towel, which is clipped to the drape at waist level. The arm is internally rotated with the elbow flexed to 90 degrees for most of the procedure. It will be accessible for examination when the exposed plexus needs to be stimulated. The head is turned to face away from the injured side. A small sandbag is placed beneath the shoulder to provide an appropriate amount of neck extension. All pressure points, particularly on the scalp, are meticulously padded. Our surgical team and anesthesiologists favor securing a nasotracheal tube with a suture, and we routinely drape the head using transparent material to facilitate monitoring the airway throughout the lengthy operation. A rectal temperature probe is used, and appropriate standard techniques for temperature maintenance are employed with vigilance.

Incision

Among experienced plexus surgeons, the choice of incision varies. Some choose to start with a single transverse incision.³⁹ We prefer to raise a V-shaped flap for complete exposure of the posterior triangle; the incision follows the posterior border of the sternocleidomastoid, gently curves just above the clavicle, and follows a line parallel to the clavicle (Fig. 53-8). This incision provides optimal exposure of the entire field of interest and prevents the need for adjustments and shifts throughout the procedure that are necessary with a transverse incision. Occasionally,

Fig. 53-7 The infant is positioned to allow the surgeon to work above, beside, and below the field. The neck is slightly extended, and the head faces away from the field. The hand and arm are accessible for observation of stimulated movements. A clear plastic drape covers the patient's face and the nasotracheal tube so that they are always visible to the anesthetist and the other members of the surgical team.

Fig. 53-8 An incision is made along the posterior border of the sternocleidomastoid and the clavicle, and a V-shaped flap is created and reflected posterolaterally. Through this exposure the entire posterior triangle is visible. For longer lesions the incision may be extended along the deltopectoral groove, if necessary.

we have had to extend the incision along the deltopectoral groove for exposure of the more distal plexus in long lesions.

Dissection

The procedure is performed under loupe magnification. The skin is elevated in the subplatysmal plane and retracted superolaterally. The lateral border of the sternocleidomastoid is identified, and the clavicular head is released from its origin. Along the lateral border of the sternocleidomastoid, the cervical plexus can be seen emerging and branching.³⁹ The branches should be neatly dissected⁴¹ (Fig. 53-9). Supraclavicular branches are often useful as graft material. As they are followed proximally while working toward the C3 and C4 roots, larger branches (the greater auricular, lesser occipital, and cervical cutaneous) can be identified. Early identification of the C4 root is helpful for proceeding with the exposure and identifying the brachial plexus roots proper (C5-T1). The omohyoid muscle divides the posterior triangle into a superior and inferior portion. The omohyoid should be divided at its tendinous midportion and reflected from the field. The dissection along the lateral border of the sternocleidomastoid can then continue. Beneath the omohyoid, a layer of adipose tissue and lymphatics is seen. This tissue directly overlies the injured plexus. It is best to mobilize this tissue as a flap by dissecting it from the lateral border of the sternocleidomastoid and then sweeping it off the clavicle in a medial-to-lateral direction. The flap, which is hinged posterolaterally, can be placed over the reconstructed plexus at the completion of the operation. The transverse cervical artery can be seen and is divided for further exposure. To prevent potential instability and the development of bone callous directly over the reconstruction, we do not divide the clavicle or remove a central segment as some do for the purpose of exposure. We generally proceed with exposing the

Fig. 53-9 The sternocleidomastoid, trapezius, and clavicle form the borders of the posterior triangle. The omohyoid divides the triangle into upper and lower portions. The accessory nerve travels obliquely. The branches of the cervical plexus are more superficial and include the lesser occipital, greater auricular, cervical cutaneous, and supraclavicular nerves. Supraclavicular branches further divide and can be useful as grafts, providing 3 to 4 cm of material.

distal plexus with the aid of an assistant, who adequately retracts the clavicle anteroinferiorly. If it is necessary to divide the clavicle, it can be restored as Borrero⁴¹ described, using a figure-of-eight suture passed through drill holes.

The plexus exits between the anterior and middle scalenes proximally. These muscles are often scarred and adhere to the neuroma on their respective sides. The anterior scalene is dissected from the neuroma, working toward the C5 foramen. Two important structures will be visible. The phrenic nerve travels inferiorly and should be carefully preserved, although any contribution from (and often to) the plexus can be divided. It is frequently scarred to the anterior surface of the neuroma.²⁶ Also directed inferiorly, but passing behind the neuroma, is the long thoracic nerve. The C5 root is dissected proximally all the way to its foramen. Dissection within the bony foramina at any level can cause bleeding from disruption of small vessels, primarily venous. This is generally controlled with time and pressure. The C6 and C7 roots are dissected next in a similar fashion. The absence of a particular root from its expected position could indicate that the root has been avulsed from the cord. The foramen should still be completely dissected to confirm this and perhaps to identify a proximal stump created by rupture rather than avulsion. The only irrefutable proof of avulsion is the identification of a dorsal root ganglion in the surgical field. The dorsal root ganglion can generally be identified by sight, appearing as a bulb of nerve tissue at the proximalmost end. If the dorsal root ganglion cannot be identified with certainty, a histologic examination is performed for a definitive diagnosis.

The upper and middle trunks, which are often difficult to separate, should be in view. Dissection of the lateral border of the plexus in a proximal-to-distal direction allows identification of the suprascapular nerve. Depending on the injury, this nerve may be seen branching from the posterior

division of the upper trunk proximally, distally, or within the zone of injury.⁴² Generally, the branching pattern of the plexus can be distorted by several factors: the length of the lesion, the presence of ruptures, the position of ruptures, and the extent that the neuroma has contracted. Contraction can be considerable, and this will alter expected branching positions. For example, the separation of the middle trunk into anterior and posterior divisions is normally retroclavicular, but this may occur more proximally in a lesion that has contracted.⁴¹ The lateral pectoral nerve, which arises from the anterior division of the upper trunk,⁴² is a useful landmark for distinguishing the anterior from posterior divisions of the upper trunk in a heavily scarred plexus. The dissection continues under the clavicle until all branches have been identified and the distal limits of the neuroma have given way to the normal branching network that will ultimately serve as graft targets.

The lower trunk, formed by C8 and T1, is dissected from distal to proximal. The subclavian artery can be found overlying the lower trunk. It should be dissected from the neuroma to be safely retracted for exposure of the C8 and T1 roots and foramina. The suprascapular artery can be intimately associated with the neuroma. It and the transverse cervical artery, which was more superficial and was already divided, are both branches of the thyrocervical trunk from the subclavian artery. Ligation and division of the suprascapular artery and vein are often necessary. Once these vessels have been appropriately addressed, the C8 and T1 roots are approached. The T1 root is smaller than the C8 root and lies posterior and inferior to it. Dissection of T1 is one of the most challenging portions of the dissection, because it lies on the parietal pleural surface. From an anterior approach, the T1 foramen is difficult to see. As the lower trunk is followed distally, all branches are located and preserved. The dissection again continues until the normal branch network distal to the lesion is identified. Unlike the upper and middle trunk components, which are often densely adherent, the lower trunk components are sometimes more easily dissected from the neuroma. The final portion of the exploration that must be completed is dissection of the posterior surface of the plexus/neuroma, which is often completed after resection of the damaged plexus.

NEUROLYSIS VERSUS RESECTION AND RECONSTRUCTION

The most common anatomic operative finding is neuroma-in-continuity, with variations in the length and the number and extent of involved roots. However, even though we see physical continuity, it is very difficult to know whether this is accompanied by regeneration of axons through the neuroma, that is, physiologic continuity. Although some authors advocate intraoperative neurophysiologic testing, we have found that functionally relevant quantification of physiologic continuity is not possible with current technologic measures. This may be why neurolysis of the plexus has not proved to be a useful means of managing obstetrical brachial plexus lesions. As Borrero⁴¹ indicated, most surgeons with experience agree that results after neurolysis alone are discouraging. Earlier in our practice, we performed neurolysis when a conducted stimulus across the neuroma produced an appropriate distal muscle contraction. We reported the results in 16 patients who underwent neurolysis, comparing preoperative active motion with that seen at the 12-month follow-up.⁴³ We observed improvement in the group of patients with upper plexus lesions, but it was ineffective in patients with total plexus palsy. We abandoned neurolysis in patients with total plexus palsy in favor of neuroma resection and grafting. Eventually, we abandoned neurolysis in patients with primarily upper plexus lesions when we recognized that infants who were treated with resection appeared to regain baseline function rapidly after resection. In 1998 we reported preoperative and postoperative active motion over time in 26 patients treated with a neuroma resection.⁴⁴ The results showed an initial decrease in function compared to the baseline. However, by 3 months no difference was noted in active motion from baseline, and by 6 months patients had either reached or surpassed the baseline. The difference could not be explained on the basis of regeneration across grafts at these early time points. Furthermore, the early follow-

up results (at 3, 6, and 12 months) were no worse for those who had undergone resection than for patients who had undergone neurolysis. Based on the observation that neuroma resection is not detrimental, and the growing body of evidence from Birch,¹² Kawabata et al,⁴⁵ Gilbert et al,^{46,47} and Aydin et al⁴⁸ that grafting offers the best opportunity for maximal functional recovery, we have strongly advocated neuroma resection and grafting as the primary management of the neuroma in obstetrical palsy.

In 2009 we published our long-term results of neurolysis versus neuroma resection and grafting with a minimum 4-year follow-up.⁴⁹ After neurolysis, patients with Erb palsy and total palsy demonstrated no improvement in function (Fig. 53-10, *A* and *C*). By contrast, patients with Erb

Fig. 53-10 **A**, Preoperative proportions of patients obtaining an Active Movement Scale (AMS) score of 6 or 7 for 15 movements of the upper extremity were compared with final proportions at least 4 years after a neurolysis for Erb palsy. (* $p < 0.05$ [McNemar exact test].) **B**, Preoperative proportions of patients obtaining an Active Movement Scale score of 6 or 7 for 15 movements of the upper extremity were compared with final proportions at least 4 years after neuroma resection and interpositional nerve grafting for Erb Palsy. (* $p < 0.05$ [McNemar exact test].)

palsy and total palsy undergoing neuroma resection and grafting had significant improvements in most of the affected upper extremity motions, as measured using the Active Movement Scale⁴⁹ (Fig. 53-10, *B* and *D*). This study provided strong evidence that neurolysis as a complete surgical treatment for obstetrical brachial plexus palsy should be abandoned in favor of neuroma resection and grafting. Neurolysis can be useful in selected patients in whom a normal fascicular pattern is demonstrated within surrounding scar. This can occur in upper trunk or upper and middle trunk injuries that result in scarring around otherwise uninjured C8 and T1 roots. However, unless a distinct, normal fascicular pattern is evident, and direct nerve stimulation produces appropriate muscle contractions, we resect all lesions and proceed with reconstruction using nerve grafts.

Fig. 53-10, cont'd **C**, Preoperative proportions of patients obtaining an Active Movement Scale score of 6 or 7 for 15 movements of the upper extremity were compared with final proportions at least 4 years after neurolysis for total palsy. (* $p < 0.05$ [McNemar exact test].) **D**, Preoperative proportions of patients obtaining an Active Movement Scale score of 6 or 7 for 15 movements of the upper extremity were compared with final proportions at least 4 years after neuroma resection and interpositional nerve grafting for total palsy. (* $p < 0.05$ [McNemar exact test].) Evaluation of the Proximal Roots

Exploration and dissection of the plexus ideally should reveal a central traumatized area, represented by a neuroma, with normal structures proximally and distally. The distal dissection should always continue until grossly normal, identifiable branches are exposed. The length of the neuromatous lesion determines whether this occurs at the level of divisions, cords, or terminal branches. We typically transect the neuroma through its midportion. Each of the distal branches is transected at a level that appears grossly normal, and the distal half of the neuroma is removed. These carefully identified ends are the targets for sural nerve grafts. Depending on its branch point location, the suprascapular nerve is usually an independent distal target. The condition, quality, and axonal topography of the distal ends are demonstrable through histologic frozen section using toluidine blue dye. This is always performed in our practice.

Proximally, a major dilemma can occur. An empty foramen, or histologic evidence of a dorsal root ganglion outside the foramen with otherwise apparent continuity, irrefutably indicates root avulsion from the spinal cord. With each avulsion, fewer proximal source stumps are available to provide axons to the distal targets. When continuity from within a particular foramen along the neuroma is apparent, how do surgeons definitively know whether the proximal stump will be a suitable source? How can we determine whether an intraforaminal avulsion has occurred, if it is not visible? This is the most vexing problem in the operation, because grafts from a stump that appears normal (grossly and even histologically) will provide no axons whatsoever if it has been avulsed from the spinal cord. The only way to know with certainty whether an intraforaminal avulsion has occurred is through a laminectomy. However, because this is generally not considered safe for infants, we must weigh all available evidence to reach a most probable conclusion. Box 53-1 presents an outline for the available evidence.⁴¹

Some of this evidence warrants further discussion. Although using MRI to evaluate root status has been advocated in recent reports,^{50,51} technical difficulty, reliance on exquisite interpretive skills, and the need for further statistical validation have limited the widespread application of MRI for determining root avulsion. We continue to investigate all infants preoperatively with

Box 53-1 Steps for Determining an Intraforaminal Avulsion

1. Preoperative data
 - a. A physical examination
 - i. The Hospital for Sick Children's Active Movement Scale (in our practice)
 - ii. The presence of Horner sign
 - b. Radiographic data: CT myelography (or MRI in some centers)
2. The muscle response to direct stimulation of the root. A normal-appearing nerve will not conduct distally if complete avulsion has occurred.
3. The operative findings: the gross appearance of the stump, tactile sensation during transection
4. A histologic examination of the proximal stump
5. Intraoperative electrophysiologic testing

CT myelography. A CT myelogram provides useful information depending on the presence of a pseudomeningocele and the ability to see rootlets traversing it. Chow et al⁵² studied 281 roots in 58 patients undergoing exploration and reconstruction. Comparing radiographic interpretation to findings during surgery, they determined the sensitivity, specificity, positive predictive value, and the likelihood ratio for these two possible indicators of root avulsion. Of 38 root avulsions, 24 were associated with pseudomeningocele, for a low sensitivity (0.63) but a relatively high specificity (0.85). For pseudomeningocele with absent rootlets, the sensitivity was even lower, but the specificity was near perfect (0.98), and the likelihood ratio was 18.5. A low sensitivity indicates that avulsion may be present without either of these findings. With high specificity, however, the proportion of false-positives, or normal roots incorrectly identified on a CT myelogram, decreases. Therefore a positive finding (a pseudomeningocele with absent rootlets) is more suggestive of root avulsion at a particular level. In other words, when rootlets cannot be seen in association with a pseudomeningocele, a false-positive (a normal root) is highly unlikely; it is 18.5 times more probable that the involved root is avulsed (Fig. 53-11). Because the sensitivity is low, further evidence is needed to rule out avulsion in the absence of these statistically specific indicators.

Recent evidence has suggested that intraoperative electrophysiologic testing is unreliable as a predictor of root avulsion. In a randomized, prospective, double-blind trial, Dupere et al⁵³ showed no correlation between the findings of an expert neurophysiologist evaluating root avulsions with somatosensory evoked potentials and surgical findings.

Histologic analysis of the root stumps before grafting has proved useful. When a neuroma is transected proximally, the site must be proximal to the injury to allow axonal growth from the stumps to coapted grafts. Visual inspection of the cut stump end is insufficient to determine the status of the proximal stump neural architecture. Redett et al⁵⁴ examined the proximal stumps after transection guided by visual inspection. The authors demonstrated that frozen-section analysis of the root stumps led to a measurable improvement in the histologic grade of the stumps after re-resection in appropriate candidates. Frozen-section analysis prompted re-resection to reach a proximal level suitable for grafting in at least one stump in 25% of patients overall.

Fig. 53-11 A preoperative myelogram, axially at the level of C8, shows a pseudomeningocele at C7-T1 (arrow). Neither dorsal nor ventral C8 rootlets are seen traversing the pseudomeningocele. This finding is a very specific indicator of root avulsion (specificity 0.98), with a likelihood ratio of 18.5 for avulsion.

Grafting

The neuroma has been resected, the targets have been identified, and their proximal and distal ends histologically deemed satisfactory. The usable (decidedly nonavulsed) proximal stumps have been selected. A gap has been created. Multiple strands of sural nerve graft will span this gap. If the supraclavicular branches of the cervical plexus have been carefully dissected, these may also serve as graft material.

Sural Nerve Graft Harvest

We elect to harvest bilateral sural nerves at the first stage of the operation (that is, before exploration of the plexus). We perform sural nerve harvest using endoscopic assistance. Capek et al⁵⁵ provided a complete description. The infant is prone for this portion of the procedure and is then placed in a supine position for exploration and reconstruction of the plexus. In this way, exposure and access are optimal, and only one change in position is required. An endoscopic-assisted harvest is performed through three 2 cm transverse incisions⁵⁵ (Fig. 53-12). The sural nerve can be harvested from its most proximal origin from the tibial nerve to the most distal branches supplying the lateral foot. In an 8 to 10 kg infant, an average of 13 to 15 cm can be harvested per leg. The harvested nerves are placed in moist, sealed, sterile containers that are refrigerated until they are needed.

Graft Reconstruction Planning

A reconstruction plan is formulated and individualized to the unique anatomic findings of each patient. Variations are seen in each of the following:

- The positions of targets distally along the branching plexus
- The number of available proximal source stumps
- The presence and extent of injury to the lower plexus
- The length of the neuroma and therefore the length of needed graft

If a target is reconstructed using grafts from its developmentally appropriate source root, then the reconstruction is anatomic grafting for that target. If at all possible, this is the first choice for reinnervation of target nerves. If, however, the appropriate source root is avulsed, then associated

Fig. 53-12 An endoscopic sural nerve harvest, as described by Capek et al. **A**, A series of three 2 cm transverse incisions are made, centered along the midline of the calf. The nerve is harvested distally along the lateral aspect of the foot and proximally to its origin from the tibial nerve, where additional length can be obtained by intrafascicular dissection. **B**, The resultant scars from harvest in this manner are generally very acceptable and prevent a long "stocking seam" incision.

targets must receive innervation from an alternate source, a procedure known as *neurotization*. This can be accomplished with remaining roots (plexoplexal or intraplexal neurotization) or from nerve donors outside the plexus (extraplexal neurotization).

The distances to every target are measured from each of the available roots. The length of available graft material (sural nerve and cervical plexus) likewise is measured. The division and allocation of graft material is prioritized. Any of the above-noted variations can present limitations, and reconstruction requires consideration of the greatest functional needs. Most investigators agree that the use of the upper extremity depends on a functioning hand. Therefore prioritization of functional motion should first focus on reinnervation of the hand.^{28,41} This is addressed using multistrand grafting to lower trunk targets. After the hand, priority is directed to elbow flexion and then to shoulder motion.

Grafts are placed into position in reversed orientation to prevent progressing axons from prematurely exiting the graft through side branches of the original sural nerve. Graft placement is performed under an operating microscope. In our practice, nerves are coapted using commercially available fibrin glue, with no sutures. Some surgeons prefer to use suture material only, and others use a single suture reinforced with fibrin glue for end-to-end coaptation.

Fig. 53-13 depicts the working plan and the final diagram for a patient with upper plexus palsy with avulsion of C8. On average, the distance from most sources to the respective targets is 2.5 to 4.5 cm, as in this case. T1 had a distinct and normal-appearing fascicular pattern and was

Fig. 53-13 This patient presented with an upper plexus palsy and was found to have an avulsion of C8, demonstrated unequivocally by the presence of a dorsal root ganglion. C5-7 was involved in a dense neuroma, and T1 had a normal fascicular pattern with minimal involvement in the neuroma. Anatomic grafting was performed to the suprascapular nerve, anterior and posterior divisions of the upper trunk, and the middle trunk. Intraplexal neurotization to the lower trunk was performed from C7. T1 was treated with a neurolysis. The phrenic nerve is shown traversing longitudinally over the plexus.

treated with a neurolysis. The remaining distal targets, including the suprascapular nerve, were reconstructed with grafts from the three intact stumps. For most targets, grafting was anatomic. Grafts to targets that had received C8 innervation (avulsed) are considered intraplexal neurotizations, because they were grafted from other available stumps.

Fig. 53-14 presents a patient with avulsion of C7, C8, and T1. In this case a longer gap was created after a neuroma resection, making strategic graft allocation even more important. The lower plexus targets were given first priority (highest priority to hand function) to receive grafts from the available C5 and C6 stumps. The lower trunk therefore was reconstructed using an intraplexal (nonanatomic) neurotization. The upper trunk targets were selected next to favor elbow flexion and shoulder function.

This case also demonstrates the use of extraplexal neurotization. The suprascapular nerve was reconstructed from the spinal accessory nerve (cranial nerve XI). This is the most commonly

Fig. 53-14 This patient presented with a total plexus palsy and was found to have avulsions of C7, C8, and T1. A long lesion was present. This was a difficult situation because of the paucity of stumps available for grafting and the long lengths of graft that were required. The lower trunk targets were given first priority to provide hand function and were grafted from the C6 stump, as was the middle trunk. The anterior and posterior divisions of the upper trunk were grafted from C5. Extraplexal neurotization of the suprascapular nerve from the accessory nerve was a useful maneuver to conserve available graft material.

performed extraplexal neurotization, according to most authors. Cranial nerve XI is dissected distally beneath the trapezius muscle to its major branch point. The dissection is performed through the existing neck exposure. The longitudinal branch supplying the thoracic portion of the trapezius is divided distally and transposed into the field, where it consistently reaches the cut end of the suprascapular nerve free of tension. Performed in this manner, the function of the cervical/upper thoracic portion of the trapezius is not sacrificed. This muscle inserts on the clavicle, acromion, and scapular spine. The suprascapular nerve provides external rotation at the shoulder through the actions of the infraspinatus and supraspinatus muscles. Tse et al⁵⁶ have shown that neurotization using the spinal accessory nerve produces external rotation at the shoulder equal to that obtained by anatomic reconstruction using sural nerve grafts from C5. Other extraplexal neurotizations include the intercostal nerves (typically two to three donors are used) and the contralateral C7 root. Before performing an extraplexal neurotization, surgeons should consider the expected potential gain in function and the donor deficit.

Postoperative Care

Postoperatively, a simple dressing is applied over the incision, and the child is fitted with a Velpeau sling made with a single length of 2-inch stockinette material (Fig. 53-15). Properly fitted and maintained, this soft, inexpensive bandage effectively maintains the arm in full internal rotation and shoulder adduction with the elbow flexed to 90 degrees.⁵⁷ We have used this technique and have appreciated its efficacy and advantages over plaster immobilization in more than 250 primary infant plexus reconstructions. Infants tolerate it extremely well, and parents and nurses can easily maintain and adjust it. A Velpeau sling is worn continuously for 3 weeks.

Complications

Both major and minor complications can occur with brachial plexus reconstruction. In our recent review of 173 brachial plexus reconstructions for obstetrical palsy, the total combined rate of major and minor complications was 33.5% (58 patients).⁵⁸ The major complication rate was 18.5%, and the minor complication rate was 15%. The incidence of complications did not appear to be

Fig. 53-15 A light dressing is placed on the incision, and a soft stockinette Velpeau-style garment is fashioned to keep the arm securely adducted, with the elbow bent to 90 degrees. The sling is worn continuously for 3 weeks. It is not necessary to employ a plaster shoulder girdle casting with this technique.

influenced statistically by the age of the patient (ranging from 3 months to 1 year). No deaths occurred. Major complications included wound infection (2.3%), seroma (1.2%), and respiratory complications of postoperative hemidiaphragm paralysis (6.4%), atelectasis (2.9%), pulmonary edema (1.7%), pleural effusion (1.7%), pneumothorax (1.7%), and chylothorax (0.6%). Accidental extubation occurred in five patients in the early part of the series. With the addition of a clear plastic head draping and suture fixation of the nasotracheal tube to the membranous septum, this has not occurred in the subsequent 100 patients. Pneumothorax was managed intraoperatively in two of the three affected patients by pleural repair and reinforcement. This was assisted by placement of a rubber catheter to apply negative pressure; repair was confirmed by a submerged Valsalva maneuver. In the third patient, a pneumothorax was identified by radiographic examination in the recovery area and was treated with aspiration.

Long-term complications associated with sural nerve harvest are minimal. In a controlled study of patients undergoing sural nerve harvest for brachial plexus reconstruction, 86% demonstrated a measurable sensory deficit in the lateral aspect of the foot at a minimum of 5 years postoperatively.⁵⁹ However, no patients reported sensory problems, and no functional implications are related to this sensory deficit.

NERVE TRANSFERS

Extraplexal and distal nerve transfers may be indicated for patients with a delayed presentation in a delayed fashion, multiple cervical root avulsions, or insufficient graft material for completing the desired reconstruction. The most commonly used extraplexal transfer is the spinal accessory to suprascapular nerve transfer to restore external rotation, as described previously.⁶⁰ Successful neurotization of the myocutaneous nerve to restore elbow flexion using the thoracic intercostal nerves or the medial pectoral nerve has been described.⁶¹⁻⁶³ Other extraplexal donor nerves include the phrenic nerve and, in the rare situation of a five-root (total) avulsion, the contralateral C7 nerve root.^{64,65}

More recently, the distal nerve transfers described for traumatic brachial plexus reconstruction in adults have been applied to Erb palsy. Al-Qattan⁶⁶ was the first to publish his results on the use of the ulnar-to-biceps nerve (Oberlin et al⁶⁷) transfer in patients with poor elbow flexion presenting later than 12 months of age.

Other surgeons have published small case series in which the ulnar or median nerve was used to neurotize the biceps and/or brachialis nerve for primary or late elbow reconstruction in patients up to 24 months of age.^{66,68-70} For restoration of shoulder motion, the triceps-to-axillary nerve transfer and the posterior approach to the spinal accessory-to-suprascapular nerve transfer have been described.⁷¹⁻⁷⁴

For many surgeons, distal nerve transfers are more appealing than proximal neuroma resection and grafting because of their greater technical ease, reduced operative time, and earlier reinnervation of the target muscle. Although distal nerve transfers play a role in selected cases of obstetrical brachial plexus palsy, caution must be exercised in adopting this approach for all patients. One of the major disadvantages of distal motor nerve transfers is the lack of sensory reconstruction. Furthermore, in upper and middle trunk injuries, selective reconstruction of elbow flexion and shoulder abduction may not enhance or restore other affected motions such as pronosupination. Without proximal exploration, the extent of the lesion may be underappreciated, and the opportunity for neurolysis of uninjured roots (for example, C8 and T1) from the scar generated by an upper and/or middle trunk injury is lost. Finally, no evidence has been reported to support the long-term functional outcomes of distal nerve transfers in Erb palsy patients. Future studies that rigorously evaluate the role of nerve transfers in primary nerve reconstruction in these patients will help to determine the indications for this approach.

CONCLUSION

Primary microsurgery for obstetrical brachial plexus lesions is a new area of surgical expertise. It offers the possibility of improved functional ability in carefully selected patients who would otherwise have lifelong impairment and secondary skeletal deformities. One major challenge in this area of peripheral nerve surgery is the selection of patients most likely to benefit from surgical intervention. Key factors for developing selection criteria and resolving other issues (such as identifying root avulsions) include consistency, accuracy, and careful reporting of natural history and outcome data. In particular, we strongly emphasize that a statistically sound method of assessment must be consistently applied from the time of presentation through long-term follow-up. Advancement, to date, has resulted from the application of evidence-based recommendations from well-designed studies. As the field of obstetrical brachial plexopathy management continues to evolve, questions will continue to be answered using such scientific methodology.

KEY POINTS

- Most patients with an obstetrical brachial plexus lesion do not require surgery.
- Determining the need for surgery is the most difficult aspect of treatment and relies on a thorough understanding of the natural history of such injuries and careful application of selection criteria.
- Selection criteria must be based on validated, objective test instruments. Such instruments should be subjected to rigid statistical analysis for the purpose of formulating a reliable prognosis.
- A detailed obstetrical history and physical examination provide useful data for determining the spinal root injury level and the proximal-to-distal extent of an injury.
- Appropriate retraction of the clavicle generally obviates the need to divide it for distal exposure.
- Neurolysis may be appropriate only for conditions in which a distinct fascicular pattern is seen within the surrounding scar; otherwise, statistical evidence indicates that neuroma resection and grafting offer the best opportunity for maximal functional recovery.
- Proximal stumps and distal targets should be histologically evaluated before grafting to determine suitability for grafting.
- Neurotization techniques vary and provide useful means of neural input to selected targets.
- A Velpau sling provides efficient and tolerable immobilization postoperatively for a recommended duration of 3 weeks.

The Toronto Active Movement Scale was introduced in this report as a statistically relevant tool for grading the severity of brachial plexus injury when establishing a prognosis. This scale may aid in the decision to proceed with surgical treatment for appropriately selected patients. As opposed to prior methodology focused primarily on elbow flexion, the scale incorporated an evaluation of a more comprehensive set of upper extremity motions.

Neurolysis alone for ubiquitous neuroma-in-continuity has had discouraging results. Led by a growing sentiment that resection and microsurgical reconstruction offer greater long-term potential, the authors demonstrated that resection of a neuroma and microsurgical reconstruction offered early results that were at least equivalent to those of neurolysis, even before reinnervation potential was expected.

Volkmann Ischemic Contracture

Ronald M. Zuker • Joseph Upton III

Volkmann ischemic contracture is a devastating injury. In children it takes two forms. The first, which is known as *neonatal Volkmann contracture*, is present at birth and is usually the result of intrauterine emboli, compression, or a combination of both. Various degrees of skin loss and muscle loss are present, requiring complex wound management and reconstruction. Secondary effects on neurologic function and skeletal growth can be devastating.

The second form, *childhood Volkmann ischemic contracture*, usually results from limb trauma, most commonly a supracondylar fracture. Forearm ischemia results, which leads to muscle necrosis and subsequent fibrosis and contracture formation. In this chapter, both forms are discussed. We describe the clinical picture, the pathophysiologic processes involved, and the management of these complex conditions, which often includes muscle replacement using microvascular techniques.

Neonatal Volkmann Ischemic Contracture

DEFINITION OF THE PROBLEM

Neonatal compression injuries and compartment syndromes causing secondary ischemic contractures are rare and almost universally misdiagnosed.¹⁻⁶ The spectrum of anatomic severity is wide and extends from dorsal skin bullae to circumferential full-thickness skin loss and ischemia of the dorsal and volar compartments in the proximal two thirds of the forearm.

This condition is not listed as a cause of compartment syndrome in the most recent edition of commonly used texts of hand surgery.⁷ We have included this condition as a compartment

syndrome because of the characteristic prenatal history and physical examination of the newborn. The pathophysiology is the same as that of compartment syndrome after arterial compromise associated with the supracondylar fracture in a child or a crushing injury to the forearm seen after trauma.

The literature on this condition consists primarily of case reports, small series, and case reports with a summary of the literature to date.⁸⁻²³ Based on the numerous reports, we advocate that this condition no longer be considered as rare, but rather one that is not easily diagnosed. This chapter is based on 49 cases I (J.U.) have seen over a 40-year period in a large children’s hospital, which is a tertiary referral center for the New England states. We conclude that this condition, especially the milder forms, is often either misdiagnosed or not recognized early in life.

Differential Diagnosis

The differential diagnosis of skin maceration leading to ulceration in newborns can be very confusing. There are no concise or comprehensive discussions in the surgical or pediatric literature, and the underlying causes of these problems are constantly overlooked. Arterial compromise is usually associated with failed arterial lines, repeated arterial or venous punctures, or trauma with kinking and thrombosis of vessels. More diffuse skin eruptions, bullae and small vesicle formation, and skin macerations and lesions are seen with various types of cutis aplasia, congenital epidermolysis bullosa, and other conditions primarily confined to the integument. Many conditions can be differentiated from neonatal Volkmann ischemia or compartment syndrome (Table 54-1).

Associated involvement of other portions of the body can yield these diagnoses. Distal arterial insufficiency resulting in amputation is often described as a vascular catastrophe and is usually associated with low-flow states in infants who are in shock or on extracorporeal membrane oxygenation machines. Extravasation of irritating intravenous infusions can cause significant local edema and potential tissue loss. In this condition, history and physical examination findings are very specific, and the extravasations are usually well documented.

Table 54-1 Conditions Differentiated From Neonatal Volkmann Ischemia		
Condition	Symptomatology	Methods of Diagnosis
Neonatal gangrene	Associated with cool limb and decreased pulses, predisposing catheterization, indwelling lines, or hematologic problems (polycythemia)	Angiography, CTA, Doppler ultrasonography
Necrotizing fasciitis	Fever, warmth, sepsis	Blood cultures, biopsy, surgery
Cutis aplasia congenital	Associated scalp necrosis, digital amputations, and hypoplasia; healed and not healed ulcers	Biopsy, clinical examination
Amniotic band syndrome (constriction ring syndrome)	Associated bands, congenital amputations, acrosyndactyly	Clinical examination
Subcutaneous fat necrosis	Associated red to blue plaques, nodules on the trunk and limbs, not present at birth	Skin biopsy
Epidermolysis bullosa	Very fragile skin with bullae	Skin biopsy, including electron microscopy studies and immunofluorescent mapping

Background Information

The name *Volkmann ischemic contracture* of the forearm may be misleading, because many newborn infants with this condition have not developed secondary contractures.^{24,25} However, the eponym is used in this chapter, because it is easily recognized and the pathophysiology is similar. Similar cases are published in the literature under the names *neonatal Volkmann ischemia*, *neonatal compartment syndrome*, *extremity gangrene in utero*, *neonatal forearm compartment syndrome*, *acute ischemia of the newborn*, *neonatal arterial occlusion*, and *neonatal compression syndrome*. Many of these cases are in the dermatologic literature listed under *cutis aplasia congenital*, which is a very specific syndrome with scalp and usually hand findings (see Table 54-1).

Genetics

Volkmann ischemic contraction has no known genetic association or predisposition. It is classified as an in utero disruption. The incidence seems to be much higher with multiple births and with amniotic fluid problems such as oligohydramnios. Isolated gestational conditions have been reported, but none are consistently found in the large cohort of patients.¹¹

CLASSIFICATION

No known classification system exists for this condition other than what we reported in the first edition of this book. Few publications have been devoted to this subject; most reports describe the initial presentation and diagnosis, and even fewer discuss specific treatment and long-term outcomes.¹⁻²³ We have separated our cases into five clinical groups (types) that are distinguished from one another by the extent of the compression of the soft tissue structures. The mildest form, type I, probably occurs more frequently but is not recognized because of the limited amount of skin pathology that is present at birth. We have not seen many of these cases clinically in our tertiary referral centers, where infants are referred for large, nonhealing neonatal ulcers. Box 54-1 describes the classification types, and Table 54-2 summarizes our classification system.

Box 54-1 Neonatal Volkmann Ischemic Contracture Types

- Type I: Partial-thickness skin bullae are present, with involvement of the dorsal extensor compartment. Arterial, neural, and skeletal anatomy is normal.
- Type II: Full-thickness skin ulcers or eschars are present, affecting both the dorsal and volar compartments. Involvement of the volar compartment is very subtle on physical examination. Contractures develop in the dorsal and volar compartments, and all patients show long-term changes in growth patterns.
- Type III: Both the volar flexor and dorsal extensor compartments are involved, and full-thickness loss in part of the dorsal compartment, with exposed periosteum, can occur. The nerves and arteries within the volar compartments are intact. Nerves can undergo compression neuropathies.
- Type IV: Much larger skin deficits signify severe compartment involvement and loss of one major artery, usually an ulnar artery, and possibly the ulnar nerve. Skin bullae and artery loss may be circumferential. Bone is exposed, and signs of digital ischemia are usually present.
- Type V: The most severe group is characterized by more extensive loss of all soft tissue and by osteomyelitis. Skin loss is circumferential. A partial or complete loss of one or more digits occurs consistently.

Table 54-2 Classification System for Neonatal Volkmann Ischemic Contracture

Type	Skin	Muscle Compartments	Nerve	Arterial (pulses)	Skeletal Early Findings	Skeletal Growth
I	Bullae only	None to one involved (usually dorsal)	Median and ulnar nerves both intact	Radial and ulnar pulses intact	Normal	Normal growth
II	Bullae; localized, full-thickness loss	Both	Both intact	Both intact	Normal	Moderate shortening (<25%)
III	Large, full-thickness loss	Both	Both intact	Both intact	Periosteum exposed	Moderate to severe (25% to 50%)
IV	Large to circumferential tissue loss	Both	One out (usually ulnar)	Both intact to one out	Cortex exposed \pm digital loss	Severe (>50%)
V	Large to circumferential tissue loss	Both	One out (usually ulnar)	Both intact to one out	Cortex exposed; osteomyelitis; \pm digital loss(es)	Severe (>50%)

PATHOPHYSIOLOGY

The primary pathologic process resulting in a contracture is an increase in pressure within a muscle compartment, producing irreversible ischemia, which leads to contracture and functional loss. Arterial ischemia may be the precipitating cause. We think this is true in 20% of our patients, who also present with cerebral embolic ischemia (neonatal stroke). Without citing the events that occur at a molecular level, we think the inciting trauma is pressure on the neonatal forearm, resulting in an increased compartment volume that leads to the familiar cascade of increased compartmental pressure, venous stasis, ischemia, muscle loss, fibrosis, and contracture. External pressure on these limbs that is greater than the normal systolic pressure will directly cause muscle necrosis. In limbs with a significant amount of myonecrosis, with or without skin ulceration, significant contractures can develop within a very short period (see Figs. 54-3, 54-4, and 54-8).

ANATOMY

The muscle and skin anatomy in these neonatal limbs is different from that seen in patients with classic, established Volkmann contracture caused by arterial occlusion. As the compartment pressure increases, the central portion of the muscle is more ischemic, and perfusion at the edges is retained. Muscle necrosis and degeneration occur more frequently in the central portion, and an elliptical band of scar forms parallel to the long axis of the forearm. The muscles most affected in the classic contracture are the deep and superficial flexors and the pronator teres. In contrast, these limbs with neonatal compartment syndrome have soft tissue damage and secondary contracture on the dorsoulnar aspect. It is localized to the direct site of compression and forms a dense block of fibrous tissue.

FUNCTIONAL CONSIDERATIONS

Because all tissues within the forearm and hand may be affected, the functional losses are wide ranging. In most established cases of pediatric and adult Volkmann contractures, the major sensory nerves are usually spared, and sensation in the hand is normal in all but the type IV and type V categories. The ulnar nerve is affected more commonly than the radial nerve. Because both the dorsal and volar muscle compartments are involved in all but the type I limbs, flexion and extension contractures are present. Forearm pronation and supination are usually limited in most and absent in severe types. In patients followed through childhood and adolescence, all but the type I limbs demonstrate growth abnormalities not only at the direct site of forearm compression but also at the distal growth plates of the radius and ulna (see Figs. 54-2, 54-6, and 54-8).

PREOPERATIVE ASSESSMENT

Maternal History

In our experience, no predisposing associated diseases, medical conditions, medications, or diagnostic procedures had complicated the early pregnancy. However, multiple births, mostly twins, was a common factor in more than a third of the cases. Labor was difficult and prolonged in all cases, and the overwhelming majority of infants were delivered by cesarean section. One infant, delivered vaginally by a midwife after a 40-hour labor, had loss of both radial and ulnar arteries resulting in the loss of all digits and both thumbs. Other factors include maternal varicella infection, gestation and insulin-dependent diabetes, prematurity, and coagulation abnormalities.

Physical Examination

Infants with Volkmann ischemic contracture are usually delivered by cesarean section. They have good Apgar scores, are neurologically intact, and respond appropriately to stimulation. Additional neurologic deficits may be seen in those with the worst deformities and include listlessness and evidence of cerebral ischemia. The most distinguishing feature of neonatal Volkmann patients is a yellow or tan eschar on the dorsal surface of the proximal forearm (Fig. 54-1). In the more severe cases, a circumferential skin eschar may be present. Extensor tightness is not typically present, because flexion contractures predominate with increasing ischemia of the flexor-pronator

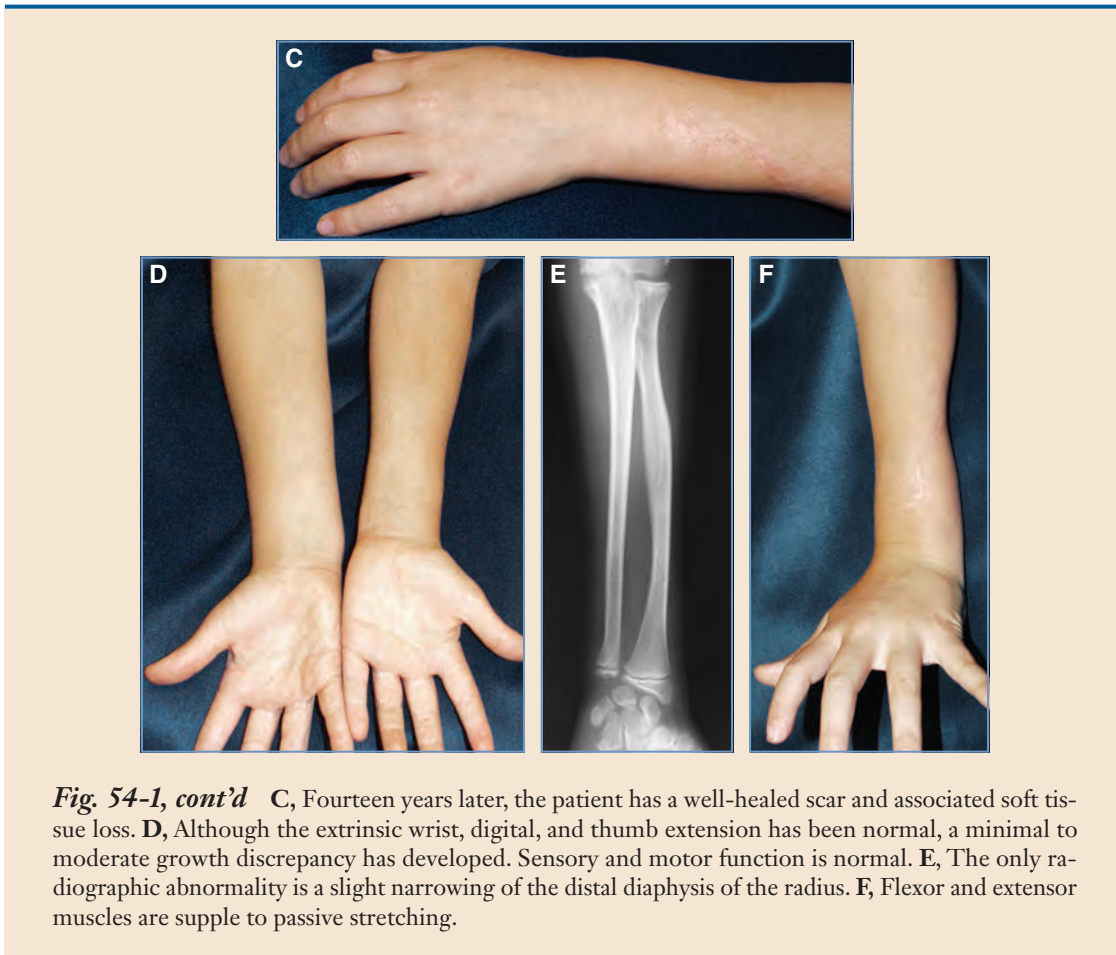

Fig. 54-1 Type I defect. **A**, After a difficult labor requiring a cesarean section, this infant was born with a bullous eruption on the dorsal left forearm that persisted as a full-thickness skin ulcer by 8 weeks of age. Simple excision and closure with an advancement flap were performed. **B**, The underlying extensor tendons and muscle groups were surrounded by early scar formation within the areolar connective tissues.

Continued

muscle masses. Shortly after birth, resistance to passive extension of the flexed digits increases. Dorsal wrist and digital extension contractures develop after the skin ulcer is debrided and is either allowed to heal by spontaneous epithelialization or covered with a split-thickness skin graft. When the periosteum or denuded cortical bone is exposed, secondary osteomyelitis will occur if the open wound is not covered appropriately.

Laboratory and Radiographic Tests

Results of all routine laboratory tests are normal in infants with the milder forms of Volkmann contracture. The white blood cell count is often elevated with large ulcerating forearm lesions, and urine myoglobin levels may be elevated in the presence of extensive muscle necrosis.

Routine radiographs of the arm and forearm usually show no significant abnormalities, but as these children begin to grow, sclerotic changes with or without narrowing of the radius or ulna occur along these tubular bones at the site of bone necrosis. The mottled changes of osteomyelitis will be present with bone exposure. The distal epiphyseal ossification of both the radius and ulna is delayed in all but type I limbs. Affected growth plates become sclerotic, irregular, and mottled depending on the degree of initial vascular damage. The extent of skeletal impairment is not clear during the first several years of life, unless complete or partial absorption of the skeletal structures occurs. In patients followed through adolescence, all of these limbs with the exception of type I limbs show an impressive amount of growth retardation.

MRI studies were not carried out in any of our patients shortly after birth. Presently, special coils and techniques would be necessary to provide cuts small enough to show adequate detail in these very small limbs (see Fig. 54-4). In the future, techniques should be available to demonstrate the amount of damage to the muscle compartments.

TREATMENT (Box 54-2)

Principles

1. Early diagnosis is essential and universally overlooked.
2. Early debridement and fasciotomy are performed for all involved muscle compartments.
3. Early coverage with split-thickness grafts or preferably full-thickness flaps for large wounds is undertaken.
4. All patients undergo an aggressive splinting and passive range-of-motion regimen.
5. Stable, full-thickness coverage must be provided before elective free muscle transfers, tendon transfers, tendon lengthening, and neurolysis procedures. Waiting until all inflammation has resolved and maximum passive motion has been achieved is ideal.
6. A careful follow-up is critical to document and treat growth-related problems.

Box 54-2 Treatment Options for Neonatal Volkmann Ischemic Contracture

Muscle

Excision of muscle fibrosis before transfers

Free muscle (gracilis, partial latissimus) transplants for wrist extension or digital and thumb flexion

Classic tendon transfers for wrist extension or digital/thumb flexion, with donors depending on potential available motors (flexor carpi radialis to extensor carpi radialis to extensor digitorum communis [index through fifth], flexor digitorum superficialis [ring to thumb])

Tendon transfers for correction of fixed supination (rerouting the biceps tendon insertion)

Tendon lengthening at the forearm level

Flexor-pronator muscle slides at the forearm level

Nerve

Neurolysis at the forearm level

Nonvascularized nerve grafts (sural donor)

Vascularized nerve grafts (sural donor)

Arterial

Revascularization of the ulnar artery with a vein graft

Skin

Excision and closure of small ulcers

Local flap closure

Split-thickness skin grafts; full-thickness skin grafts

Pedicled groin or abdominal flaps

Free fasciocutaneous (anterolateral thigh, scapular) or myocutaneous (latissimus dorsi, gracilis) transfer

Skeletal

No treatment

Nonvascularized autologous or cadaveric bone grafts

Epiphyseal transfers (fibular head)

Vascularized bone grafts for nonunions (fibula, medial femoral condyle)

No distraction lengthening because of the excessive amount of scar tissue

Options

Although each affected limb in these infants is different, the early treatment for all groups is similar. Patients with these wounds, which do not heal by secondary intention, are usually referred to either a hand surgeon or a plastic surgeon for skin graft coverage. Elbow, wrist, and digital contractures in severe cases are treated aggressively with passive exercises and splinting. Infections are treated with topical and intravenous antibiotics. Numerous soft tissue and skeletal procedures have been performed in these children.

Preferred Treatment

Type I

Cleaning and local wound care are the only treatments needed in this group. Splinting and passive range-of-motion exercises may be necessary for subtle contractures within the extensor compartments.

Type II

In patients with type II, early recognition and release of tight extensor compartments will preserve muscle function. Small ulcers can be conveniently excised and closed with local or regional flap transfers of full-thickness tissue. Splinting and exercising should be started early. Progressive flexion contractures are best treated with tendon lengthening at the distal forearm instead of flexor slide procedures. We prefer to perform precise tendon lengthening at the myotendinous juncture in the forearm. The scar and secondary contracture or contractures generated by flexor slide procedures can be very troublesome. Symmetrical growth deficiencies of the forearm do not require treatment, and excessive ulnar deviation can be corrected with lengthening and bone grafting. Skeletal shortening at the forearm level will occur, often without obvious radiographic changes. No treatment is necessary.

Type III

In patients with type III, early debridement of nonviable tissue and appropriate fasciotomy of both extensor and flexor muscle groups are critical. Contracted scars from healed wounds or skin grafts should be excised and replaced with healthy, full-thickness tissue before major reconstruction is performed. Dense scars and nonfunctional fibrotic muscle (usually extensor) are best excised to prevent progressive muscle contracture. Tendon lengthening, bone grafts, and neurolysis are then carefully individualized to each limb and functional deficit.

Type IV

In patients with type IV, early debridement, fasciotomy of all muscle compartments, and revascularization of major vessels should be performed soon after birth (see Fig. 54-7). Recognition, proper diagnosis, and appropriate referral to a hand surgeon or plastic surgeon are essential. Intrinsic muscle releases are performed in swollen hands caused by major arterial blockage. Full-thickness flap replacement for heavily scarred areas should precede reconstruction for restoration of extension by free muscle transfer. Supination contractures are corrected with rerouting of the biceps tendon (see Fig. 54-5), and progressive tightness of the digital flexors is corrected by step

lengthening in the distal forearm. Repositioning of the forearm and creation of active flexion are the primary functional priorities. Well-vascularized skeletal and cartilaginous structures in the distal forearm are retained, because they may include an intact growth plate of the radius or ulna.

Type V

Early treatment of patients with type V is the same as treatment for those with type IV, with amputation of nonviable digits or thumb. All possible functional muscle should be saved, and full-thickness flap coverage of the skin-deficient areas is preferred. Neurolysis of scarred nerves and sural nerve grafting for intercalated nerve loss is performed to restore sensation in the ulnar and occasionally the median nerve distributions. When the radial nerve is so badly injured that grafting is not practical, free muscle transfer for active wrist extension is preferred to tendon transfer of scarred muscle-tendon units. Repositioning the wrist and the hand in the functional “position of advantage” is best accomplished with joint release and full-thickness skin grafting. These hands will be used as helping limbs as long as sensation is intact.

SPECIFIC TREATMENT CHALLENGES

Neonatal Volkmann ischemic contracture has no standard treatment. More patients are being correctly diagnosed and treated either at the time of birth or shortly after birth. Options for corrective surgery and/or splinting depend on the extent of the soft tissue and skeletal damage. Early treatment needs to be aggressive, because the tissue damage is always much greater than originally anticipated unless the treating physician has seen this condition previously. These accelerate with growth for all types except type I.

Patients with types IV and V losses present some of the most difficult reconstructive hand problems. Because sensation is present in these hands, they are worth salvage despite their incipient growth problems. Replacement with full-thickness soft tissue is always better than with skin grafts, which have a propensity for contracture. Free muscle transfer will substitute for the complete loss of an entire compartment, but tendon transfer in these forearms can be performed as long as the donor muscle has a good excursion and is not heavily scarred. Motor nerve identification is the most critical portion of the free transfers. Extensive neurolysis is invariably needed with remarkable return of sensation, which is not seen in adults. The hand often has intact metacarpophalangeal flexion and interphalangeal joint extension through intrinsic muscles, and thenar and hypothenar musculature is usually intact. Only the extrinsic flexors or extensors are lost. Very little can be done for patients with distal digital losses or hypoplasias. We have not performed toe transfers in these patients. Most of these children request arm and/or forearm lengthening as teens or preteens. We have performed lengthening procedures in 11 of our 49 patients over the past 40 years. The distractions have been staged, consisting of initial distraction to the desired length, followed by removal of the uniplanar device, bone grafting, and internal fixation. All have been successful, but complications were higher, including nonunion and delayed union despite bone grafting, and pin tract problems. Progress is much slower, because distraction is performed across a dense cicatrix involving soft tissue and bone.

The major goals in these severely affected limbs is to maintain motion at the shoulder, elbow, and wrist; to provide length for no other reason than appearance; and to best position the sensate hand for function. The most difficult patients are those who had intrauterine strokes affecting the uninjured side. In these patients, reconstructing the injured limb is paramount.

OUTCOMES

Information about outcomes in this group of patients is scarce.¹⁻²⁷ Most reports present the initial presentation, diagnosis, and debilitating growth disturbance. None of these children, including those with a type I limb, have completely normal forearms and hands. Those with severe neonatal ischemia have very compromised limbs. Despite the limitations, these hands are much more effective than a below-elbow prosthesis. Future reports with long-term outcomes should be forthcoming.

Type I

In patients with type I, the partial-thickness dorsal skin defects often heal spontaneously and result only in tight, hypopigmented scars. Tightness within the extensor musculature is treated with physical therapy. This is the only group without secondary growth problems (see Fig. 54-1).

Type II

In type II patients, a contracted scar or indolent ulcer on the dorsal surface of the proximal forearm can usually be excised and closed with local flap advancement. Subtle tightness within the flexor and extensor compartments can be adequately treated with splinting and stretching during the entire period of growth. Although grip strength is diminished, patients have few glaring functional impairments. Total tendon excursion at the wrist is decreased, and the tenodesis effect of the flexors and extensors with wrist range of motion can be exaggerated. Sensation is normal. Intrinsic muscle function within the hand is normal. Growth changes will result in moderate shortening (less than 25%) of the forearm (Fig. 54-2).

Fig. 54-2 Type II defect. **A** and **B**, After a difficult arrested labor, this infant was born with circumferential bullae involving the middle and distal thirds of the forearm. The entire forearm and hand were markedly swollen. No compartment releases were performed. **C**, A deep ulcer on the dorsal surface was the last area to heal by spontaneous epithelialization. At that time, the extensors were described as absent and the extrinsic flexor/pronator group as very tight. A splinting-stretching exercise program was initiated.

Fig. 54-2, cont'd **D**, At 9 years of age, the patient continues to have a very swollen arm with very limited wrist extension and tight extrinsic flexors of the forearm, which she cannot supinate because of the tight pronator teres muscle tendon unit. A moderate-to-severe arrest in longitudinal growth has occurred. **E** and **F**, Radiographs show no marked changes in the appearance of these tubular bones and growth plates on the right side. This forearm and hand are used primarily in a helping capacity.

Type III

Dorsal forearm wounds that either heal spontaneously or are covered with a graft will contract progressively and impressively. Aggressive stretching and splinting are more effective for the dorsal muscle compartments than for the flexor-pronator group, which often requires tendon lengthening. The hand and wrist can have marked deviation in the radial or ulnar direction with growth disturbances, resulting in forearm bones of unequal length. Osteolysis and resorption of standard corticocancellous grafts and vascularized bone grafts are increased, causing the deviation. Centralization procedures may be more predictable. The process of distraction-lengthening of short forearms when performed later in childhood and adolescence is different than distracting normal forearm bones. The large, contracted scar in the original zone of injury causes delayed skeletal unions, nonunion, and an often-difficult, slow distraction. Sensation should be intact. The vascular blood supply to the hand is intact. The moderate-to-severe shortening of the forearm bones is usually heralded by increased sclerosis and narrowing, which are seen early in childhood on routine radiographs. Tendon lengthening of the flexor-pronator group will alleviate the progressive tightness of these muscle groups and improve the gripping potential of the hand, which should have a mobile wrist. A diminished tendon excursion of the extrinsic flexors and extensors decreases the grip and causes difficulties with independent extensor function of the digits and occasionally the thumb (Fig. 54-3).

Fig. 54-3 Type III defect. **A**, This infant was delivered by cesarean section and had a yellow, parchmentlike eschar on the dorsal middle and distal thirds of the left forearm. The scab was sequentially debrided by a pediatric surgeon, who let the entire wound heal by secondary intention. **B**, She was first seen shortly after her second birthday with limited flexion and extension of the thumb and digits and severe ulnar deviation of the carpus and hand. **C**, The very tight scar on the dorsoulnar forearm was excised, and the region was resurfaced with an ipsilateral pedicled groin flap. Although sensation in the ulnar nerve distribution was intact, the ulnar artery was not in continuity. The flap was detached and inset 3 weeks later. **D** and **E**, The hand was realigned, and the loss of the distal ulna was corrected with a free vascularized fibular transfer. The peroneal artery was anastomosed as an intercalated segment between the ulnar artery in the proximal forearm and Guyon's canal distally. Additional vessels supplying the fibular head were anastomosed separately. **F**, Visible changes in the distal radius and its growth plate were evident on plain radiographs when the patient was 3 years of age.

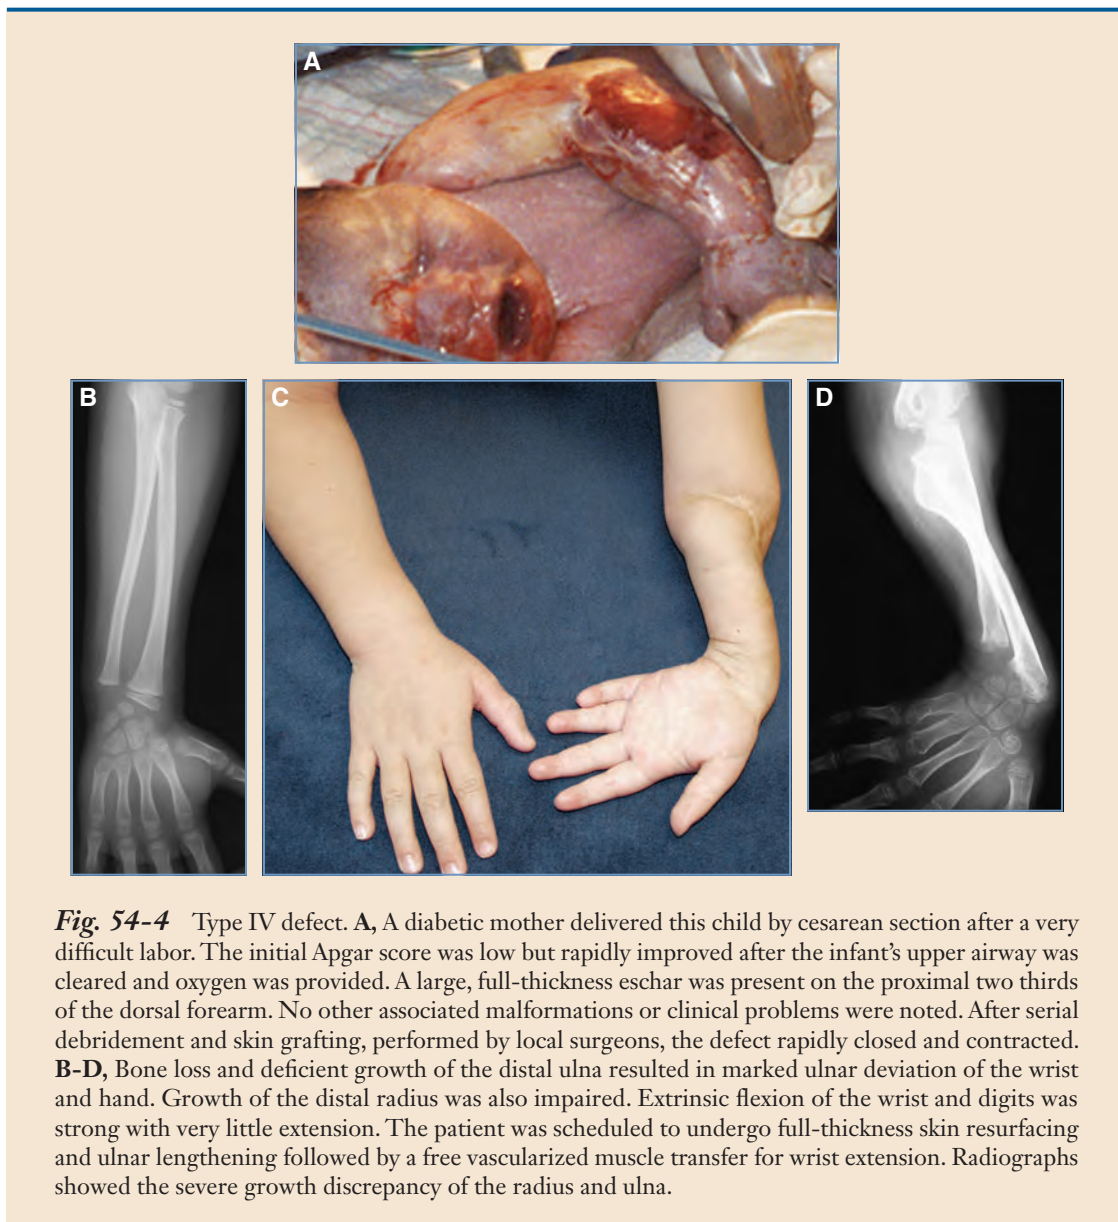

Fig. 54-3, cont'd G and H, Her floppy forearm and persistent nonunion persisted. She wore a forearm splint at all times. Sensation in the hand was normal. Ulnar-innervated intrinsic muscle function was absent. I, The longitudinal plate was reapplied, and another nonvascularized bone graft was performed. The second graft also failed to heal completely. J-L, Her last procedure was a two-segment free fibular transfer, in which one segment was placed within the nonunion, and a larger segment was placed along the entire ulnar border of the forearm. This graft has healed uneventfully and stabilized the patient's forearm and wrist. She continues to use this forearm and hand in a helping function and has always been right-hand dominant.

Type IV

All of the adverse outcomes seen in the type III category are predictable in patients with type IV. The arms, wrists, and hands of these patients are never normal. Skeletal changes are apparent early in childhood, and the diminution of growth is severe. Distraction lengthening is difficult. Distal ischemic changes in the hand can result in partial or complete digital loss. One patient with radial artery loss and an incomplete palmar arch had a complete thumb loss (see Fig. 54-5). Digital and thumb range of motion is often affected, and grip, key pinch, and independent precision function of the hand are affected to varying degrees. These children adapt to their functional

Fig. 54-4, cont'd E-G, Serial forearm radiographs obtained at 4 months, 2 years, and 7 years of age demonstrated early epiphyseal mottling, irregularity, and very deficient growth of the distal ulna and radius. H, Sagittal MRI at 7 years showed marked loss of skin, subcutaneous fat, and all local muscle groups.

deficits and develop many ingenious compensatory motions just as those with congenital malformations do. The results of early neurolysis of scarred nerves or intercalated nerve grafting are excellent for return of protective sensation. The return of intrinsic muscle function in the hand in these situations is unpredictable. Those with one-vessel forearms may demonstrate varying degrees of cold intolerance in colder northern climates. Many of these children do not complain, even though the affected forearms and hands become quite mottled and erythematous when exposed to the cold. This is not unusual in these children, who have adapted to both their lack of mobility and altered sensation since birth. This is normal to them. Because the cicatrix from the original zone of injury is much greater, outcomes after muscle slide and tendon lengthening are poor to fair at best. Free muscle transplantation is more predictable (Fig. 54-4).

Type V

Type V limbs function as helping extremities at best. Young children often neglect digits without sensation, which are subject to injury, maceration, and infection. The initial wounds are often circumferential and result in tight, contracting scars early in life. Often, major portions of potentially functional muscles and their motor nerves are debrided. Bone loss, usually ulnar, frequently results in severe deviation at the wrist level. The motion of most joints within the hand and wrist is affected, and growth is frequently diminished. The digits and thumbs with intact sensation and good extrinsic and intrinsic muscle function will grow most predictably.

Despite the devastating effect of these ischemic injuries involving almost all skeletal and soft tissue structures of the forearm, these children adapt very quickly to their deficiencies and make the best of potential function (Figs. 54-5 through 54-9).

Text continued on p. 1662

Fig. 54-5 Type IV defect. **A-C**, This infant was born vaginally after a very difficult and prolonged labor. By 2 weeks of age, she had a full-thickness eschar. The mother had gestational diabetes and toxemia of pregnancy. The wound was debrided over the next 3 weeks, and the granulation bed was covered with a split-thickness skin graft by a pediatric surgeon. **D-G**, The clinical appearance and radiographs of the patient's right and left forearms and hands at 22 years of age. The reconstruction consisted of pedicled flap coverage of the entire dorsal forearm at 3 years of age, a free gracilis muscle transfer for wrist extension at 7 years of age, an osteotomy and lengthening of the radius at 9 years of age, and re-routing of the biceps tendon for correction of a fixed supination contracture. She has had normal sensation, intact radial and ulnar arteries, and tight flexor tendons for her entire life.

Fig. 54-6 Type V defect with distal digital loss. **A** and **B**, This 6-year-old child was born with a circumferential eschar that was debrided and skin grafted within the first 3 months of life. The avascular thumb was amputated. Despite several releases, the severe extension contractures have persisted; in addition, the patient had secondary boutonniere deformities involving all four remaining digits. This hand is minimally functional. **C** and **D**, MRA scans showed normal trifurcation of the brachial artery at the elbow. Only the ulnar artery was in continuity. The interosseous and radial arteries were blocked at the distal forearm level and reconstituted with collateral circulation to fill the common digital vessels to the digits. There was no evidence of either an intact superficial or deep palmar arch.

Fig. 54-7 Type V defect with dorsal and volar compartment loss. **A** and **B**, This child's mother reported abnormal fetal movement 2 days before giving birth by cesarean section. The child, a dizygotic twin, was born with circumferential blistering around the entire forearm and is shown at 2 days of age. There was a 22-hour delay in making the proper diagnosis. By that time, the entire hand and all of the digits were swollen and very painful to passive extension. **C** and **D**, In a forearm and hand fasciotomy, nonviable lemon-colored muscle was observed in the dorsal and volar compartments (*arrows*). The maximal compression was located on the dorsal surface of the proximal and middle thirds of the forearm. None of the blistered skin survived.

Fig. 54-8 Type V defect with allograft transplantation. **A**, This monozygotic twin was born by cesarean section, with circumferential discoloration and bullous eruptions on both forearms. The child had severe vascular compromise of the ulnar half of both hands for the first 3 weeks of the life. **B**, When first seen at 5 weeks of age, the patient had large, open ulcers of the dorsal and ulnar surfaces of both forearms, along with exposed tendon and bone. **C** and **D**, Impressive contractures and extensive soft tissue loss had already developed. A 6 cm area of ulnar diaphysis was exposed and infected. **E**, A preoperative angiogram revealed a brachial artery feeding a one-vessel (ulnar artery) forearm and an intact palmar arch within the hand segment. **F**, The extent of the soft tissue skin and muscle loss was appreciated after scar debridement, fasciotomy of all dorsal and volar compartments, and contracture release. No normal skin was debrided. **G** and **H**, The forearm, wrist, and hand were covered with a free latissimus dorsi myocutaneous flap at 6 weeks of age. The thoracodorsal artery was anastomosed end to side to the 1.5 mm brachial artery at the elbow level.

Fig. 54-8, cont'd **I-K**, A large intercalated defect within the ulna remained after multiple debridements. The distal ulna was originally intact, with vascularized cartilage with a growth plate. Shortly after the infant's father tragically died of a ruptured intracerebral aneurysm, a portion of his radius and radial nerve was transplanted as allografts to reconstruct the ulna and ulnar nerve. She was maintained on a low-dose immunosuppressant for 10 months after the transplantation. **L-N**, At 20 years of age, the free latissimus flaps used to resurface both forearms have expanded with growth, which is impaired on both forearms. Although longitudinal growth of both radii exceeds that of either ulna, forearm length is markedly diminished. **O**, The twins at 19 years of age, with the affected woman on the *right*. Thumb and index finger pinch are good in both hands. She has no wrist extension or digital extension of the ulnar three digits, which show evidence of vascular impairment. Thumb and index finger extension are present. Light touch and 4 mm, moving, two-point discrimination are present in both ulnar nerve distributions.

Fig. 54-9 Type V defect with stroke. **A** and **B**, This child presented at 5 years 4 months of age with a marked length discrepancy of his right upper limb. He was born with a major ischemic injury and a large eschar on the dorsoulnar surface of the forearm, which healed spontaneously. The shoulder was high positioned. The elbow and wrist were unstable. He had good shoulder and elbow motion. The wrist was flail. Radiographs showed that, with growth, the distal ulna completely resorbed, and the radius became sclerotic with a deformed, angulated distal metaphysis. The phalanges had thin, pencil-like condyles and hypoplastic distal segments. **C**, The hand appeared swollen and was much smaller than the opposite hand. Although the hand wrinkled in water, he had diminished sensation in the medial nerve distribution. **D**, An MRI T2-weighted scan showed an ischemic defect in the distribution of the middle cerebral artery.

Childhood Volkmann Ischemic Contracture

The childhood form of Volkmann ischemic contracture is a clinical condition resulting from muscle necrosis and subsequent secondary shortening and contracture. The muscle necrosis and loss often lead to a significant functional deficit. This, combined with tightness and contracture formation, can reduce hand function to a minimum. Volkmann²⁴ first described the condition in 1869. Classically, the contracture follows a supracondylar fracture. Circulatory embarrassment occurs, which can lead to compartment syndrome, as described later in the chapter. The end result is a pronated forearm with the wrist flexed, the thumb adducted, and the metacarpal phalangeal joints extended. The interphalangeal joints of the fingers and thumb are flexed. Most cases of childhood Volkmann ischemic contracture can be prevented by appropriate management of the supracondylar fracture and early recognition and treatment of developing compartment syndrome. Once established, however, the management becomes extremely complex and difficult. In severe cases, a variety of reconstructive techniques, including microvascular functioning muscle transplantation, are possible. However, even with the sophisticated reconstructions available today, normality can never be restored. Thus, prevention is paramount, and additional, more effective management techniques should be sought.

CAUSES AND PATHOGENESIS

Knowledge of the anatomy of the forearm is helpful for understanding the causes and pathogenesis of Volkmann ischemic contracture. Most cases result from a supracondylar fracture with a subsequent untreated or inadequately treated compartment syndrome. The forearm musculature is encased in a thick fascial envelope. With decreased perfusion, the enclosed musculature swells. However, the fascial envelope limits swelling and leads to further ischemia. A vicious cycle of increasing ischemia begins, leading to further edema and reduced circulation. Eventually, circulation in the muscle is severely diminished, resulting in muscle necrosis. This reduced arterial input is known as *Volkmann ischemia* and is basically a process of myonecrosis. If unrelieved, irreversible muscle death will occur. To relieve the pressure, the compartment is opened through fasciotomies. The ischemic muscles rapidly tighten and shorten. Over the course of several weeks, the forearm and hand take on the classic characteristics of Volkmann ischemic contracture. In severe cases, the tight volar forearm musculature tightens the tendons, deforming the fingers and resulting in an immobile hand of minimal functional value.

Lesser degrees of involvement occur, but most cases are severe. For children and older (not neonatal), Lipscomb²⁶ has classified Volkmann ischemic contracture into four categories according to the severity. Grade I is mild with good muscle function that is only minimally reduced. Nerves are not involved. Grade II is moderate with considerable loss of muscle function but no nerve deficit. Grade III is severe with only minimal residual muscle function. Some degree of nerve deficit is typical. Grade IV is severe with no muscle function and significant nerve deficit. From a clinical standpoint, most treated cases are grade III or IV. Some patients with grade I are not recognized.

PREVENTION

Volkmann ischemic contracture is a condition that should not occur in modern surgical practice. Appropriate treatment of supracondylar fractures and early recognition and treatment of any suspected compartment syndrome are essential. Surgeons should be on alert with high-risk patients, such as those with displaced supracondylar fractures. Managing these fractures involves closed reduction with fluoroscopic control and insertion of percutaneous K-wires. The reduction is maintained with the K-wires, and the elbow can then be extended, thus minimizing the chance of reduced arterial flow in the brachial artery. Even with appropriate reduction, adequate fixation, and the elbow in extension, extreme vigilance is needed to recognize the signs and symptoms of a compartment syndrome. Monitoring children for symptoms that are cause for concern is imperative. These include increasing pain in the forearm, reduced sensation in the hand, reduced arterial input to the hand, and increased swelling and tenseness in the forearm compartments. Surgeons should monitor the vascularity through the radial and ulnar pulses and watch for increasing forearm discomfort, particularly with passive extension of the fingers. With passive stretching of the fingers, the musculotendinous units are placed under some degree of tension and will be extremely painful if an ischemic process is under way. Flexing the fingers will be extremely painful if forearm ischemia is present. If compartment syndrome is suspected, the tense, intracompartmental pressure is measured. This is easy to perform at the bedside with a wick catheter or a slit catheter technique. If the intracompartmental pressures exceed 30 mm Hg, decompression by fasciotomy is indicated.

Fasciotomies are carried out as soon as possible and as completely as possible. Volkmann ischemic contracture can involve not only the volar compartments, but also the dorsal compartments. Thus these are monitored and decompressed if necessary. Early decompression can interfere with the vicious cycle of muscle ischemia, swelling, and necrosis. However, when muscle is ischemic

at room temperature for longer than 6 hours, a full recovery is not possible.^{27,28} Thus timing is critical, and compartment syndrome release should be considered a high-priority emergency. The fasciotomy wound is left open and closed later, when muscle swelling has diminished. The wound can be closed with a variety of skin closure devices or a skin graft. Occasionally, the skin graft can be excised at a later date with the aid of tissue expansion. Although the forearm can scar after this is done, upper limb and hand function are preserved.

MANAGEMENT OF ESTABLISHED VOLKMANN ISCHEMIC CONTRACTURE

The goal of managing an established Volkmann ischemic contracture patient is to restore as much function to the extremity as possible. A thorough patient evaluation is performed, and reconstruction of the injured tissues is planned.

Clinical Assessment

A detailed history is obtained, including previous surgical procedures, with particular attention to surgical debridement. Distinguishing the involved nerves is difficult when the tissues are necrotic. These have at times been mistakenly debrided. The functional impairment as perceived by the patient and family is documented. A detailed physical examination is performed that includes all structures in the forearm and hand from the circulatory system to the nerves, muscles, joints, and soft tissues. As noted in Table 54-3, the arterial input should be assessed by brachial, radial, and ulnar pulses, as well as angiography. An angiogram can provide valuable information about the anterior interosseous vessels. These are the key vessels involved in muscle transplantation. They lie beside the key nerve that will innervate the muscle, namely, the anterior interosseous nerve. Thus an angiogram is useful not only for assessing the continuity of the brachial, ulnar, and radial arterial systems (Fig. 54-10), but also for obtaining valuable information about previous damage to the anterior interosseous nerve. If an angiogram shows a healthy, pristine anterior interosseous artery, then the anterior interosseous nerve is probably uninjured. The vessels will be used as the recipient vessels in a muscle transplant procedure, and the nerve will be used as the motor nerve to innervate the muscle transplant.

Table 54-3 Clinical and Laboratory Assessment		
Structure	Clinical Examination	Laboratory Evaluation
Arterial input	Pulses and Doppler	MRA and angiogram
Venous outflow	Observation and Doppler ultrasound	Angiogram
Nerves	Median, ulnar, and radial nerve testing	EMG Nerve conduction studies EMG of pronator quadrates
Muscle function	Testing of each muscle	EMG
Joint function	Active and passive range of motion	Radiographs
Soft tissues	Scar limits movement Provision for gliding	MRI

Fig. 54-10 An angiogram showing the anterior interosseous vessels.

The major nerves to the forearm are assessed. A clinical examination of the median, ulnar, and radial nerves may be aided by EMG and nerve conduction studies. Very often, diminished nerve function is related to an ischemic process that has involved the nerves, similar to the process of myoneural necrosis. When the nerve is heavily encased in scar, it is sometimes helpful to release the scar with a neurolysis to provide additional motor and sensory function in the distal component of the extremity. When median and/or ulnar nerve function is absent, a physical defect in the nerve should be suspected and reconstruction considered. Motor nerve function can also be evaluated by EMG of the pronator quadratus muscle. This muscle lies distal in the volar forearm; therefore, if its function is confirmed, it is very likely that the anterior interosseous nerve will be functional. They are both branches of the median nerve, and some degree of active EMG activity is indicative of a functioning nerve even in the face of extensive muscle damage from the ischemic process. If uncertainty persists regarding the function of a needed motor nerve, a nerve biopsy may be helpful. This becomes particularly important in patients with a high arm or axilla injury.

Nerve reconstruction is probably best performed before motor reconstruction, with the aim of obtaining a sensate hand. Often, nerve grafting is needed to correct a significant nerve gap. All muscle groups are carefully evaluated. Even a flicker of motion is important to document. This often indicates that even though most of the muscle is necrotic, the motor nerve to the muscle is functioning. This can be crucial information when planning a muscle reconstruction.

Adequate mobility of the wrist and fingers is essential. This may be limited by the tightness of the contracture, and attempts should be made to improve the range of motion through rehabilitation. If the tendons are tight, it may only be possible to achieve partial joint mobility, but surgeons should attempt to improve this as much as possible. It is futile to provide a new motor nerve to a joint if the joint is stiff. Thus it may be necessary to surgically release tight, immobile joints before a muscle reconstruction is attempted.

The presence of extensive tightness in the volar soft tissues should be fully evaluated (see Table 54-3). Soft tissue tightness can not only limit passive joint mobility, but also impinge on muscle contraction and tendon gliding. Thus it may be necessary to provide an adequate soft

Fig. 54-11 A pedicled flap in preparation for a muscle transplantation.

tissue cover and release all soft tissue tightness. This can be accomplished with a distant pedicle flap (Fig. 54-11) or a free tissue transfer.

Patients with Volkmann ischemic contracture should undergo a psychosocial assessment. The child and family should be given realistic expectations regarding reconstruction and a detailed outline of the postoperative requirements. A well-motivated patient is essential. A rather complex and time-consuming rehabilitation program will be needed to ensure maximal gain from the reconstruction. Considerable rehabilitation will be necessary; therefore the patient needs to be compliant and the family prepared to work with the child during the postoperative rehabilitative phase. Otherwise, the gain will be only minimal.

Preoperative Procedures

A variety of factors are considered before a reconstruction of a Volkmann ischemic contracture. First, the vascular input needs to be addressed. A defect in the brachial artery should be corrected to achieve maximal inflow to the forearm and hand (Fig. 54-12). A sensate hand is important to achieve before any form of motor reconstruction is attempted. Thus median and ulnar nerves need to be in continuity, with their functional potential optimized. This may involve neurolysis, nerve grafting, or nerve transfer. The joints that will be activated by a muscle reconstruction need to have adequate range of motion. Capsulotomies may be necessary before motor reconstruction is undertaken. The soft tissues should be in optimal condition to provide adequate muscle contraction and tendon gliding.

Preoperative physiotherapy is often helpful to achieve as much mobility to the forearm and hand as possible. Pronation and supination of the forearm are emphasized. This is frequently a very difficult problem to address after muscle transplantation. If mobility is not possible, then the forearm should be placed in the most functional semipronated position. Attempts should be made to improve forearm pronation and supination. To do this, a tight pronator teres muscle may require release. In addition, the pronator quadratus in the distal forearm is often tight and limits supination. The next structure that can be involved is the interosseous membrane. This may require an incision to provide passive supination. Last, the tight capsule around the head of the radius might need to be released. Even with these four procedures, the amount of active supina-

Fig. 54-12 An angiogram reveals a defect in the brachial artery.

tion and pronation gained is often disappointing. However, even a small amount of movement is worthwhile and will provide a base on which to build.

When the circulation optimized, the sensory input is optimized, and the joint and soft tissues are fully mobilized, then additional active muscle function can be provided. Free-functioning muscle transplantation to the forearm has revolutionized the care of childhood Volkmann ischemic contracture.^{29,30} Although far from providing normal function, it can upgrade the usefulness of an extremity enormously. This procedure is the backbone of reconstruction of severe Volkmann ischemic contracture in childhood and is described in detail in the next section.

Muscle Transplantation

History

The onset of microsurgical free tissue transfer ushered in a new era of reconstructive surgery. It was not long before researchers and microsurgeons recognized the possibility of functioning muscle transplantation. In this procedure a muscle is transplanted to a different part of the body and revascularized as in other free tissue transfers, and it is reinnervated and appropriately positioned so that it will function. In 1970 Tamai et al³¹ reported on a successful transplantation of the rectus femoris muscle to the forelimb in a dog model using microneurovascular techniques. Both electrophysiologic and clinical evidence of muscle contraction and function were presented. This formed the basis for ongoing research and development in this field. In 1973, at the Sixth People's Hospital in Shanghai, microsurgeons transplanted a lateral portion of the pectoralis major muscle in a patient with Volkmann ischemic contracture.³² This was the first successful clinical application of functioning muscle transplantation. Remarkably, the patient achieved a good range of finger motion and substantial grip force. Kubo et al³³ carried out further confirmatory research in 1976, showing a virtually normal histologic appearance after muscle transplantation. In 1976 Harii et al³⁴ documented the role of functioning muscle transplantation for the rehabilitation of facial paralysis. They transplanted the gracilis muscle to the face with innervation from the healthy ipsilateral motor component of the fifth nerve.

Ikuta et al³⁵ reported on the reconstruction of Volkmann ischemic contracture by functioning muscle transplantation in a 6-year-old child. Manktelow et al³⁶ performed a functional transfer to the forearm using the gracilis and pectoralis major muscles. In 1991 Zuker et al³⁰ described their results of functioning muscle transplantation in Volkmann ischemic contracture in children. In seven patients the gracilis muscle was used for forearm reconstruction. All seven children achieved

independence in terms of daily living and significant functional improvement, particularly relative to static grip and pinch patterns. Some, however, had persistent difficulty with fine motor function, which was largely related to a lack of intrinsic hand capabilities. All children had limb length discrepancies despite open growth plates. Numerous other investigators have demonstrated an improvement in function to the forearm and upper extremity after functional muscle transplantation.³⁷⁻⁴³

Indications

Muscle transplantation for Volkmann ischemic contracture is indicated when a significant functional gain can be achieved with the addition of a single functioning muscle.^{44,45} Often, the extensor compartment is damaged, and the muscle is weakened and unsuitable for a tendon transfer. Transplantation of a muscle from a distance can significantly improve function, particularly that related to long finger grip. As with tendon transfers, the prerequisites for muscle transplantation involve adequate proximal stability of the limb, adequate ability to appropriately position the hand, and a virtual normal range of passive mobility of the wrist, fingers, and thumb. At a minimum, protective hand sensibility and preferably normal sensibility should be present. Last, the soft tissue should be adequate to provide tendon gliding at the site of tendon repair in the distal forearm. Equally important to all of these physical prerequisites is a well-motivated, determined patient with sufficient resources for intensive follow-up and postsurgical rehabilitation. If the physical and psychosocial prerequisites are met and a single, functioning muscle will significantly improve function, a muscle transplant is indicated.

As mentioned previously, other procedures may be necessary before a functioning muscle transplantation is performed. These will optimize the early and late success of the transplantation. Circulatory disruption should be repaired. A damaged brachial artery may require grafting to improve the arterial input to the forearm. Nerve gaps need to be corrected by either direct coaptation or nerve grafting. A minimum of protective sensibility should be present in the hand to improve function with a muscle transplant. Muscle contraction cannot move immobile joints. Thus these need to be addressed and adequate passive range of motion achieved. Tendon gliding is optimized with healthy flap coverage in the distal forearm (see Fig. 54-11). In addition to all of these physical prerequisites, enrolling the child in a detailed rehabilitation program may be helpful. Concepts of what will be needed after surgery should be provided and realistic goals set.

Surgical Technique of Muscle Transplantation to the Forearm

The surgical procedure for reconstruction of the forearm musculature after Volkmann ischemic contracture is difficult and complex. A two-team approach is best. The gracilis muscle is ideal for such a transfer from both an anatomic and physiologic perspective.⁴⁶ The concept of functioning free muscle transplantation in various locations in the upper extremity is similar in principle and is described here for the finger and thumb flexors. These principles can be easily applied to the finger and thumb extensors, the elbow flexor (biceps), and the shoulder abductor (deltoid).

The surgical preparation of the forearm can be difficult and tedious because of extensive scarring and previous surgical debridement. The incision along the volar forearm should be carefully planned. In the proximal forearm, the incision should adequately expose the medial epicondyle and the neurovascular recipient structures. In the distal forearm, skin flap coverage will be required for coverage of the tendon repairs to facilitate tendon gliding (Fig. 54-13, A).

Generally, beginning the dissection proximally where healthy undamaged tissue can be identified is preferred. The dissection continues distally using the median nerve and brachial artery as a guide for the depth of dissection. Preserving any large superficial vein in the proximal forearm is helpful, because it may be preferable to a vena comitans of the deeper vasculature. For finger and thumb flexion, the best nerve to use is the anterior interosseous nerve, which is a branch of

the median nerve. Adjacent to its takeoff from the median nerve are the anterior interosseous vessels, which can also provide an excellent vascular supply for the transplanted muscle. The anterior interosseous vessels and nerve are exposed by transecting the insertion of the pronator teres. This is reflected to reveal the neurovascular bundle. Even in severe cases of Volkmann ischemic contracture, stimulation of small areas of residual musculature may be possible. Using the nerve stimulator on the anterior interosseous nerve, residual musculature may contract somewhat. This will not be effective clinically, because it does not produce movement. However, it will confirm the viability and functionality of the anterior interosseous nerve. Thus this maneuver can be very important and very reassuring to surgeons.

Once the anterior interosseous nerve has been clearly identified and the anterior interosseous artery prepared, attention is turned to the central and distal forearm. The skin flaps should be elevated in a fashion that ensures no tension on the muscle with closure. In the incision in the distal forearm, it is particularly important to provide a skin flap for coverage over the tendon repairs. As the distal forearm is entered, the profundus tendons are identified. The superficialis tendons can often be divided, because they are not useful in this procedure. The profundus tendons are divided and then sutured to one another in a balanced fashion. In this way, when traction is applied to the tendons, the fingers move down into the flexed position in unison. The flexor pollicis longus is identified and divided in the forearm. If it is to be incorporated into the single muscle transplant, then it should flex slightly after the fingers. This ensures the thumb will not be caught in the palm and will not decrease the effectiveness of grip. It should flex after the fingers to provide thumb-index finger apposition. The flexor pollicis longus is then sutured to the

Fig. 54-13 A, A volar forearm incision.

balanced, four profundus tendons, and the preparation of the forearm is complete. Much of this dissection can be done under tourniquet control. However, an adequate arterial supply for vascularization of the muscle should be confirmed as the tourniquet is deflated. With the tourniquet deflated, a functioning anterior interosseous nerve is confirmed by stimulation and observation of contraction of the residual muscle.

In unusual cases in which the anterior interosseous nerve is not available, branches of the ulnar nerve that innervate the ulnar profundus tendons may be used as a second choice.

In some situations, having a degree of independence of long finger flexion and thumb flexion is helpful. This may be possible with the use of the anterior interosseous nerve. This nerve courses distally, giving off separate branches to the profundus and separate branches to the flexor pollicis longus. The branches that go to the profundus course ulnarly. The branches that go to the flexor pollicis longus course radially.⁴⁷ Thus the motor components for finger flexion can be separated from those for thumb flexion. It may be possible to separate the fibers according to fascicular territory when transplanting the gracilis muscle. In this way, the surgeon can create a separate longitudinal section of muscle with its tendinous unit, innervated by a separate fascicle. With appropriate positioning and identification of the motor components and tendinous components, the thumb function and the finger function can be separated to some degree (Fig. 54-13, *B*).

The volar forearm is now fully prepared. The medial epicondyle has been exposed, and this will anchor the muscle origin. The motor nerve to be used has been carefully prepared and confirmed to have adequate function. Often, a neuropathologist can confirm the presence of healthy axons by a quick section evaluation. Adequate vascular input is ensured by releasing the tourniquet and testing the arterial flow. A superficial vein is often helpful where a deep vein is not present or is involved with extensive venous communications. In the distal forearm, the four profundus tendons are divided and sutured in unison with a side-to-side woven technique. Traction on this unit produces finger flexion in unison. The flexor pollicis longus may be incorporated into the profundus tendon if a single, nonsplit gracilis transplant is to be carried out. The thumb is incorporated. It should lag slightly behind the unified finger flexors. If a split-gracilis muscle transplant is planned, then the anterior interosseous nerve is appropriately split and dissected, and the finger and thumb flexors are left separate.

Gracilis Muscle Preparation

Using a two-team approach, the muscle is harvested simultaneously with the forearm preparation. Many muscles have been used for transplantation, but the gracilis appears to be the best choice for forearm reconstruction because of its anatomic and dynamic physiologic characteristics. It has an appropriate anatomic configuration with a muscular belly proximally and a tendinous insertion distally.⁴⁸ With intrafascicular nerve stimulation, the gracilis can be split into two distal myotendinous units. This may be suitable for providing at least partial independence of finger versus thumb flexion. The gracilis is ideal for transplantation because of its neurovascular structures. It has a dominant pedicle with a single artery and vena comitans and a large, single motor nerve. As a strap muscle it provides adequate strength and excursion for forearm reconstruction.

The gracilis muscle lies in the medial thigh just posterior to the adductor longus. It originates at the pubis and ischium as it courses distally along the inner thigh. It inserts through a strong tendon just posterior to the tibial tubercle on the medial shaft of the tibia. The origin of the adductor muscle is easily palpated in the upper inner thigh. This provides the landmark for the gracilis incision. The incision is made just posterior to the adductor longus, and the muscle interval between the adductor and the gracilis can often be palpated in thin patients (Fig. 54-13, *C*). This incision should parallel this muscle interval in the upper inner thigh and course distally to the junction of the middle and distal thirds of the thigh. The dissection proceeds deep toward the muscle, which is usually easily identified. The neurovascular pedicle is then approached by

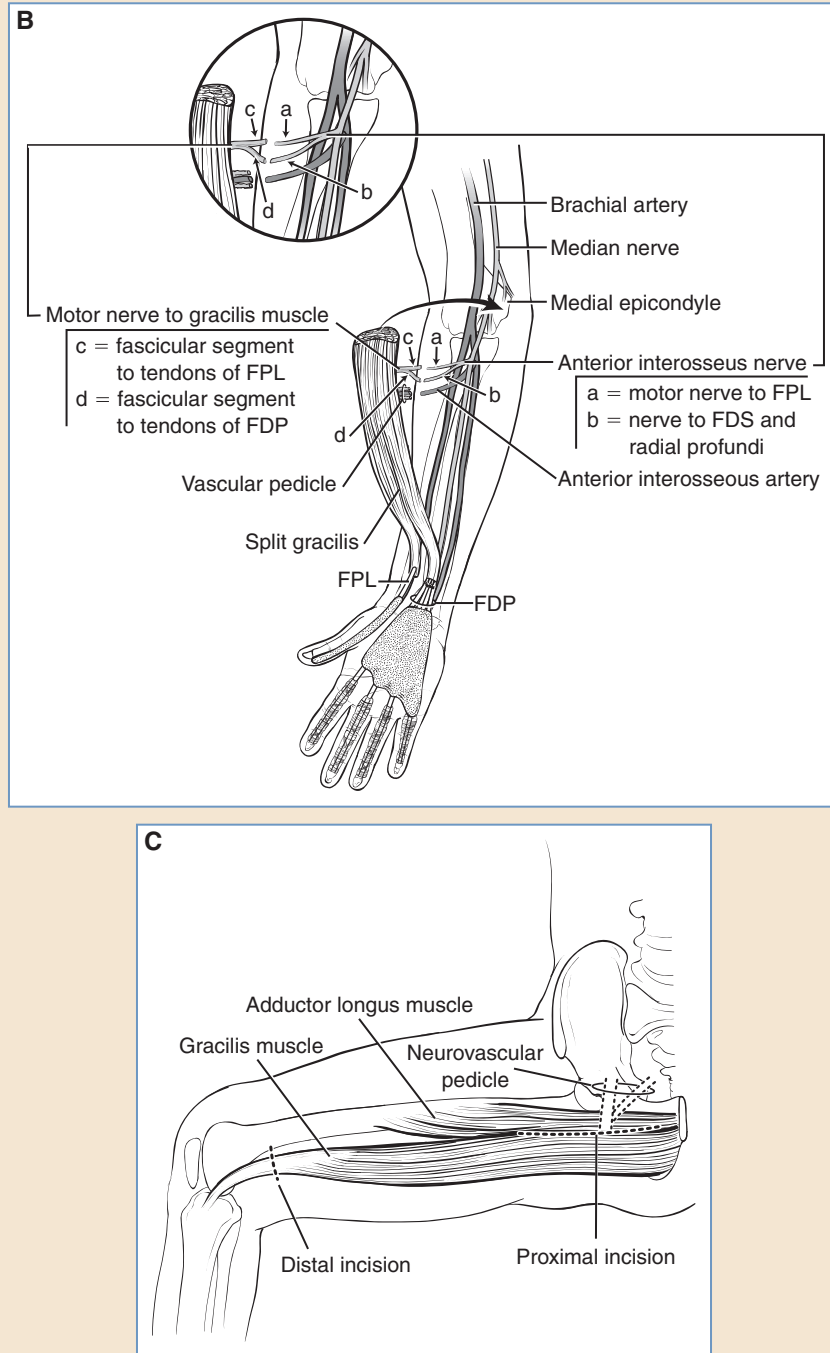

Fig. 54-13, cont'd B, Separation of function for thumb and finger flexion. The inset shows an expanded view of the neurovascular pedicle of the gracilis when the muscle is transferred to the forearm for microvascular anastomosis to the anterior interosseous vessels and microneural coaptation to the anterior interosseous nerve. **C**, Incisions for harvesting the gracilis muscle. (FDP, Flexor digitorum profundus; FDS, flexor digitorum superficialis; FPL, flexor pollicis longus.)

elevating the adductor longus anteriorly. As the adductor longus is elevated, the vascular pedicle comes into view. It generally enters the muscle approximately 8 to 12 cm from its origin and onto the deep surface. This is the major pedicle. It has a dominant artery and two venae comitantes. The motor nerve enters the pedicle just proximal to the vessels at a 45-degree angle. The vascular pedicle is dissected back to easily identifiable branches going upward into the adductor longus. These are divided, and the rest of the pedicle is easily visualized going deeper to its takeoff from the profunda femoris artery with its vena comitans. Very often, the paired venae comitantes unite at the takeoff from the profunda femoris vein.

The entire gracilis is elevated from the thigh except for its origin, tendinous insertion, and neurovascular pedicle. Marking the muscle at this stage to provide tension guides after transplantation is essential. The muscle is placed in a fully stretched position by abducting the hip and extending the knee. Markers are placed at 5 cm intervals with the muscle in this position. This can be done with sutures that will be readily identified after transplantation (Fig. 54-13, *D*).

The motor nerve to the gracilis is a branch of the anterior division of the obturator nerve (L2-3). It takes an oblique course between the adductor longus and adductor magnus. In general, this nerve contains two or three fascicles, and, with intraoperative stimulation, each fascicle can be stimulated and the appropriate motor territory observed. This can be facilitated by palpation of a portion of the muscle with individual fascicle stimulation. The myotendinous units are split distally and separated. They are seen pulled out to length in Fig. 54-13, *E*. With stimulation of one fascicle, one segment of the split muscle contracts (Fig. 54-13, *F*). This separation has potential use for the reconstruction of independent finger and thumb flexion.

After the markings have been placed at 5 cm intervals along the course of the muscle, and the distal tendinous segment of the gracilis is divided if necessary, the origin to the muscle is divided (Fig. 54-13, *G*). This leaves the muscle attached only by its neurovascular pedicle. Only when the forearm dissection is complete and ready to receive the transplant should the neurovascular pedicle be divided. This minimizes muscle ischemia.

The muscle is removed from the thigh and transplanted into the forearm (Fig. 54-13, *H*). The donor site in the thigh is closed in layers. The fascia is closed loosely to reduce the likelihood of muscle herniation. Usually, a suction drain is placed.

The muscle is positioned in the forearm to minimize the distance between the nerve repair and the muscle itself. This will reduce the time required for innervation and assist the return of adequate muscle function. Placing the muscle in the appropriate position for nerve repair allows adequate placement of the muscle belly over the medial epicondyle for the origin and placement of the tendon over the distal forearm for the insertion. The surgeon stretches the muscle to its fully extended position, as indicated by the tension guide sutures. The origin and insertion are visualized and the muscle bellies and/or tendon shortened to facilitate optimal positioning of the muscle.

Repair of the Neurovascular Structures

The muscle origin is then securely fixed to the medial epicondyle, and the neurovascular structures are repaired. Under an operating microscope, the pedicle of the gracilis is prepared. The larger vena comitans is isolated and prepared for microvascular anastomosis. This vena comitans often needs to be separated from the artery to facilitate repair. The microvascular venous repair is carried out first to either a superficial vein in the proximal forearm or the vena comitans of the anterior interosseous artery. Next, the artery to the gracilis is repaired to the anterior interosseous artery. These small vessels require technically perfect anastomoses with every attempt made to prevent thrombosis. Revision is possible but increases the ischemia time and the likelihood that the muscle will be irretrievably damaged. After revascularization is carried out, the entire muscle should appear healthy and revascularized and should contract on direct stimulation. This is often the best guide to muscle viability at this stage of revascularization.

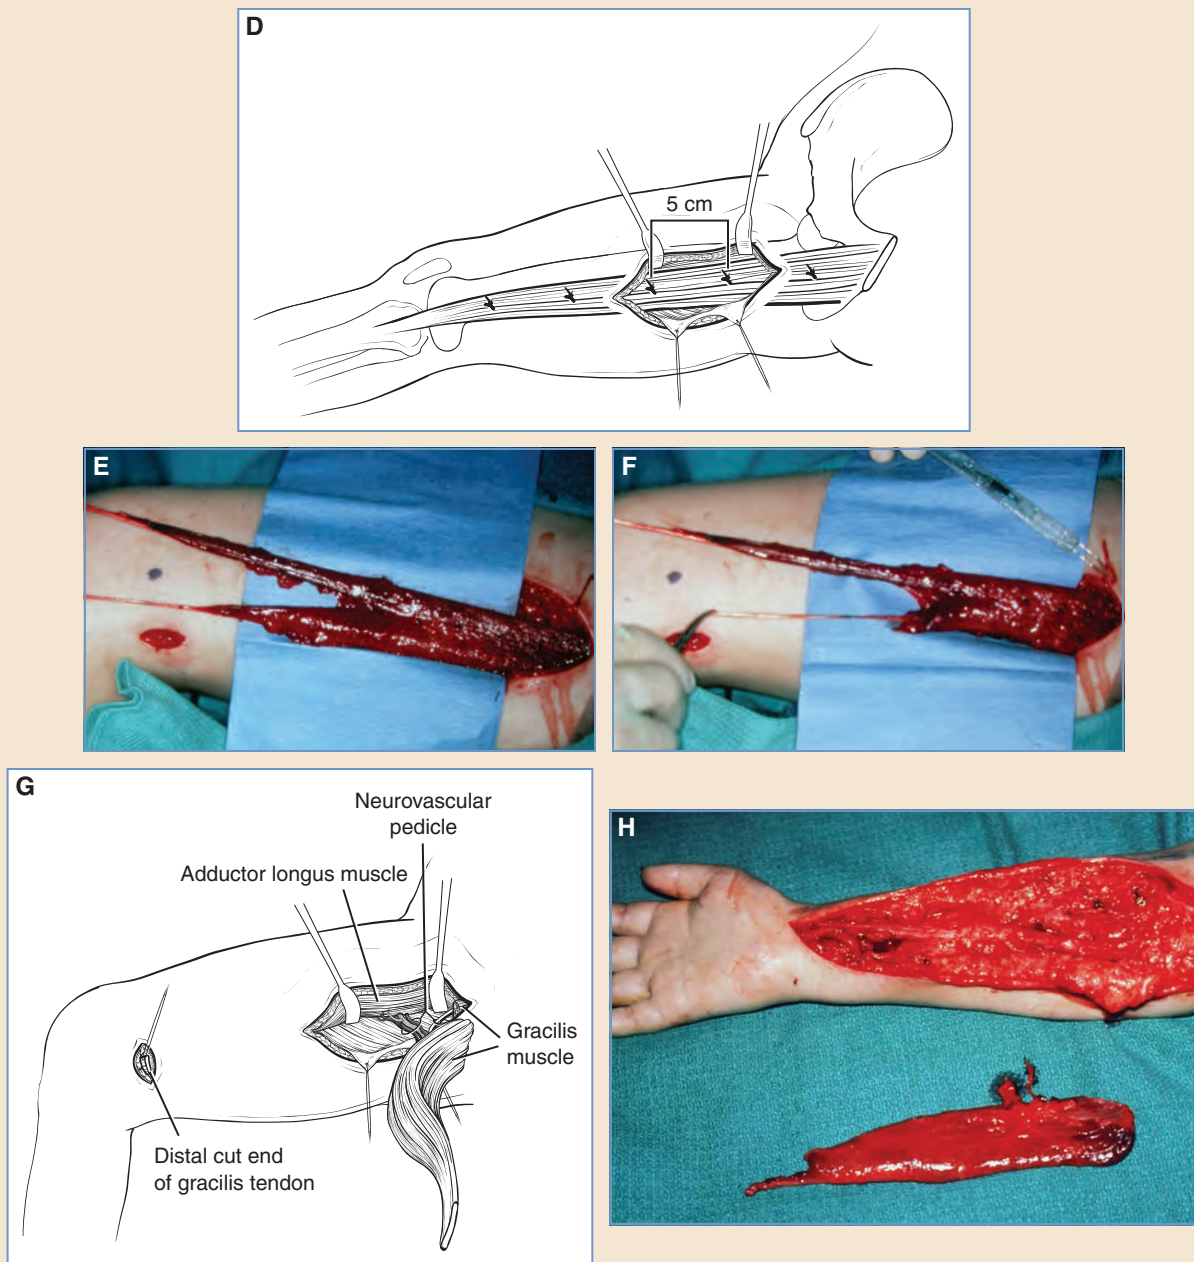

Fig. 54-13, cont'd **D**, Tension guide sutures are placed at 5 cm intervals on the fully stretched muscle. **E** and **F**, Segmental contraction of the gracilis muscle with individual fascicle stimulation. Muscle segments are pulled to length (**E**). A single fascicle is stimulated, selectively contracting one segment of muscle (**F**). **G**, Harvest of the gracilis muscle. **H**, Muscle is removed from the thigh and ready for insertion in the forearm.

The motor nerve is then repaired. This is done as close to the gracilis muscle as possible to minimize reinnervation time. The fascicles are accurately aligned under high magnification and tacked together as perfectly as possible. If a split gracilis is required, then the nerve repairs are evaluated very carefully. The fascicle of the anterior interosseous nerve that innervates the profundus is coapted to the fascicle of the gracilis motor nerve that innervates the section of the gracilis that will flex the finger. Similarly, the fascicle of the anterior interosseous nerve that innervates the flexor pollicis longus is coapted to the fascicle of the gracilis motor nerve that innervates the section of the gracilis that will flex the thumb. These nerve repairs should be perfect, under no tension, and as close to the muscle as possible.

Tendon Repair

Before the tendons are repaired, the muscle is stretched to its fully extended position, as indicated by the previously placed tension guide markers. The wrist and the fingers are also fully extended, and the location of the tendon repair is noted (Fig. 24-13, *I* and *J*). In this way, wrist and finger extension will be possible, and the muscle will flex at its most mechanically advantageous position. The site of tendon repair is marked. The wrist and fingers can be brought into a flexed position and a woven, secure tendon repair carried out without tension. If a split gracilis is required, then the portion of the gracilis tendon that will be used for finger flexion is woven through the balanced profundus. The portion of the gracilis that will be used for thumb flexion is woven through the flexor pollicis longus. The thumb flexor should be in a slightly more lax position relative to the fingers. With contraction, the thumb will not be pulled prematurely into the

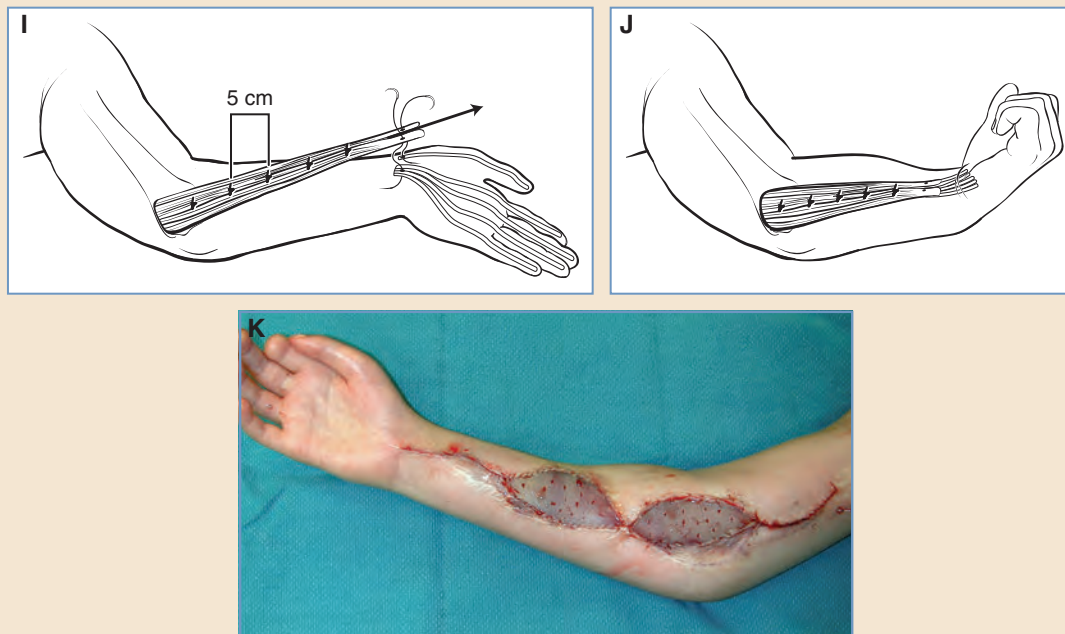

Fig. 54-13, cont'd **I**, The muscle in the forearm is pulled to the length confirmed by tension guide sutures and by the site of the marked tendon repair. **J**, The tendon of the gracilis muscle is repaired by the woven technique to balance the tendons of the forearm at the designated site. **K**, The position of the extremity on completion of the transplant.

palm, which would diminish grip. Placing the muscle under appropriate tension is exceedingly important for optimizing muscle function.

The site of tendon repair is covered with soft tissue. A healthy flap over this site will allow tendon gliding. On the other hand, the muscle belly can be covered with split-thickness skin grafts to prevent excessive bulk that can be caused by flap coverage. The adjacent skin flaps on either side of the incision can be used to cover the crucial areas of the vascular and neural repairs, with the central segment of the muscle belly left open with split-skin coverage. Drains are placed at a distance from the vascular repairs. At the completion of the procedure, the extremity is immobilized. It is preferable to have the elbow at 90 degrees and the wrist slightly flexed to relieve tension from the origin and insertion of the muscle. The finger metacarpophalangeal joints are maintained in a flexed position of 90 degrees, and the thumb is abducted with the interphalangeal joint slightly flexed (Fig. 54-13, K).

Postoperative Care: Childhood Volkmann Ischemic Contracture

As in any free tissue transplant, optimizing circulation during the early postoperative phase is critical. Thus a high-circulating blood volume, with a stable blood pressure and a hematocrit at optimum viscosity for tissue perfusion, is essential. The limb should be placed in a slightly elevated position and the patient gradually mobilized from bed rest to a chair to ambulation over a period of several days.

As indicated previously in this chapter, rehabilitation is essential for the success of the operation. The collaborative efforts of the patient, physical therapist, occupational therapist, and the surgeon are needed. For the first 3 weeks postoperatively, the extremity is splinted in a position that relaxes the tendon repairs distally and the site of muscle belly fixation proximally. This is followed by a 3-week period of gradual passive exercises. Initially, the fingers and wrist are brought into full extension with the elbow flexed. Then the elbow is fully extended with the wrist and fingers fully flexed. Over the next 3-week period, the fingers, wrist, and elbow are simultaneously extended. After this, a second 3-week period of gradual passive exercises is carried out. Initially, the fingers and wrist are brought into full extension with the elbow flexed. The elbow is then fully extended with the wrist and fingers fully flexed. During a third 3-week period, the fingers, wrist, and elbow are simultaneously extended. In this manner, after 9 weeks, the patient has undergone full passive mobilization. At this stage, the beginnings of active muscle contraction will become evident. When active muscle contraction begins, beginning active exercises to gain excursion and minimize adhesions, particularly distally, is critical. As the muscular contraction increases, the digital and thumb excursion should also increase. Active exercises with resistance should be started as soon as it is possible. This will further increase excursion and strength in particular. The entire rehabilitation program may be of ongoing benefit for up to 1½ years, until it plateaus. Both patient and family involvement are essential.

Complications: Childhood Volkmann Ischemic Contracture

Because these procedures are long and complex, particular care should be directed toward patient safety. The children must be well padded intraoperatively and kept warm. Pressure sores are prevented by constant vigilance during the procedure and during the early postoperative phase. Surgical complications can be either early or late. Bleeding can be a problem in the early phases in a densely scarred and highly vascular dissection. Infection can occur during long surgeries with open wounds. Routine intraoperative and postoperative antibiotic coverage is necessary. Wound breakdown and delayed healing can occur in these large wounds. Surgeons should anticipate a degree of delayed wound healing and not let this interfere with the rehabilitation program.

Late complications are more common; of significance are tendon adhesions at the site of tendon repair. In a series of seven patients, Zuker et al³⁰ noted that three tenolyses were necessary.

The likelihood of this complication can be reduced by early passive digital movement, but this may not be very easy in a young child. The second major late complication is wrist flexion deformities. The transplanted forearm flexor is more powerful than the extensors, leading to a fixed flexion deformity. This can be counteracted with splinting during the early phases. However, as growth continues, children undergo growth spurts that can lead to a wrist volar contracture formation. Thus diligence, particularly during growth spurts, with splinting of the wrist in neutral or extension, is extremely important. Patients should be observed and followed until their growth is complete. Even with appropriate diligence and splinting, volar wrist contractures can develop and may require such measures as serial splinting, serial casting, and even surgical intervention to facilitate realignment.

Results: Childhood Volkmann Ischemic Contracture

The results of muscle transplantation in patients with Volkmann ischemic contracture have been extremely rewarding. Muscle contraction usually begins 2 months postoperatively, and improvement is seen up to 1½ years after surgery. The main benefit is finger and thumb flexion, thus improvement in grip strength (Fig. 54-14). Results vary, however, from patient to patient. Many factors account for these differences. First, factors that affect the overall function of the extremity include the severity of the initial injury and particularly the condition of the median and ulnar nerves in the hand. These greatly influence a child's ability to perform fine movements of the hand, which are controlled by the intrinsic musculature. Second, the clinical course after the initial injury can be very influential. Open wounds can become desiccated after a fasciotomy, decompression, and debridement, leading to further necrosis and increased scarring. Infection leads to further tissue destruction and fibrosis. Joints that are allowed to become stiff are considerably more difficult to mobilize. Third, the technical aspects of the muscle transplant itself can influence the results. Perhaps most important are muscle positioning and tension. If the muscle is too tense, the digits will be flexed and even passive extension will be restricted. If it is too lax, the full effect of muscle contraction will not occur. The muscle must be viable; thus technically perfect microvascular repairs and continuation of muscle perfusion must be ensured. The motor nerve that will innervate the transplant needs to be healthy and appropriate for the function desired. The technical microneural coaptation must be perfect. After transplantation, the extremity is properly immobilized to prevent dehiscence and stretching of the tendon repairs. Patients must begin and comply with a graduated, controlled rehabilitation program to gain as much function as possible.

Barring significant complications, complete viability and function of the muscle can be expected. An excellent range of finger flexion can be anticipated, with proper positioning of the

Fig. 54-14 A classic preoperative appearance with the wrist in slight flexion, the metacarpophalangeal joints in extension, the interphalangeal joints in flexion, and the thumb in adduction.

Fig. 54-15 Postoperative photos of a patient who underwent a gracilis muscle transplantation to the forearm to restore finger and thumb flexion. **A**, Full wrist and finger extension with no volar tightness. **B**, Full finger flexion. **C**, A powerful gross grasp. **D**, The bulk of the gracilis muscle is evident on contraction.

Fig. 54-16 A secondary tenolysis is performed to gain greater digital excursion.

muscle. The distance of the finger pulp to the palm should be 3 cm or less.³¹ A perfectly coordinated grip is not a realistic expectation when the muscle transplant is used for both finger and thumb flexion. However, the finger excursion should be within 3 cm of the palm, and the thumb should flex slightly later than the fingers (Fig. 54-15). The thumb should not flex in advance of the fingers and interfere with grip.

When palpable muscle contraction is adequate but digital excursion is not, a tenolysis at the site of the tendon repair may be very useful. This can be anticipated in almost 50% of cases.³¹ This procedure frees the tendon repair from unwanted fibrous adhesions and allows greater excursion (Fig. 54-16). However, great care is required to protect the vulnerable median and ulnar nerves from inadvertent injury. If muscle tension is too lax because of inappropriate positioning or tendon stretching, a tendon-shortening procedure may be helpful.

With a successful transplant, muscle power will approach 50% of normal in an adult but only 25% of normal in a child. This significant difference is probably a reflection of testing techniques and compliance in the rehabilitation program (Fig. 54-17).

Fig. 54-17 Late results of a gracilis muscle transplantation in a patient with Volkmann ischemic contracture. **A**, Full extension with minimal flexor tightness. **B**, Adequate flexion for an effective grip, with the thumb in an appropriate position.

Fig. 54-18 Unresolved problems after Volkmann ischemic contracture in a child can include a limb-length deficiency.

UNRESOLVED PROBLEMS WITH CHILDHOOD VOLKMANN ISCHEMIC CONTRACTURE

Despite the success of muscle transplantation to the forearm for Volkmann ischemic contracture in children, many significant problems remain. Because the growth plates are very vulnerable to ischemic damage, a limb-length discrepancy can occur (Fig. 54-18). This is often compounded by extensive scarring throughout the forearm. There is currently no effective solution to this problem. Limb lengthening, although highly successful in other situations, often leads to an unacceptable functional loss in the forearm in an already compromised limb.

A second problem involves the loss of pronation and supination. Extensive scarring along the length of the forearm bones restricts movement and can significantly compromise the positioning of the hand. Even with major releases and insertion of interposition materials, major limitations persist.

Last, the delicate balance of the musculature of the forearm is often irreparably damaged. The transplanted muscle on the volar surface may overpower the weakened extensors. With time, and particularly with growth spurts, the wrist may be pulled into flexion. The persistent pressure on the wrist can lead to a significant bony malpositioning of the carpal bones. Therefore surgeons should anticipate problems with wrist flexion throughout the remaining growth of the forearm bones, especially during the growth spurts. Night splinting and even serial casting may be required to minimize this potentially devastating complication.

KEY POINTS

Neonatal Volkmann Ischemic Contracture

- Proper management requires early diagnosis and treatment.
- The less severe injuries involve the dorsal muscle groups.
- Early fasciotomy on both the dorsal and the volar compartments is necessary; volar compartment injuries are often not recognized.
- All necrotic muscle is removed, but muscles with any degree of function are not debrided.
- Neurolysis of the median, ulnar, and radial nerves is worthwhile.
- Newborns' wounds are skin grafted, but full-thickness coverage is provided before multiple, complex, secondary reconstructive procedures are performed.
- Skeletal growth will be abnormal in all but type I injuries.

Childhood Volkmann Ischemic Contracture

- Distraction lengthening should not be performed.
- Prevention is the best treatment.
- Deep volar components are the most severely affected.
- The process can affect volar and extensor surfaces.
- Angiograms are useful to not only define vasculature but also to indicate the condition of the anterior interosseous nerve.
- Stage-setting procedures will optimize outcomes.
- Muscle transplantation can be effective to provide flexion, extension, or both.
- Providing digital balance and appropriate muscle tension during a functioning muscle transplantation is crucial.
- A powerful, healthy motor nerve should be selected.
- Compliance with splinting and a concentrated rehabilitation program is essential, emphasizing the importance of patient selection.

Pediatric Soft Tissue and Bony Sarcomata of the Extremities: Considerations and Reconstruction

*Karen W.Y. Wong • Sevan Hopyan • Gregory H. Borschel
Ronald M. Zuker*

arcomas are a heterogeneous group of tumors of mesenchymal origin. Osteosarcoma, Ewing sarcoma, and rhabdomyosarcoma are the most common pediatric sarcomas, accounting for 14% of pediatric malignancies.¹ Although the prognosis for metastatic disease remains poor with 5-year survival rates of less than 30%,²⁻³ 5-year survival rates for localized disease have improved over the last 30 years, from 10% to 70% in osteosarcoma² and from less than 10% to 50% in Ewing sarcoma.³ In rhabdomyosarcoma, 5-year survival is as high as 94%.⁴

The management of pediatric sarcomas requires a multidisciplinary approach, including a wide range of surgical expertise, depending on the site of presentation, medical oncology, radiation oncology, radiology, pathology, rehabilitation therapy, nursing, and psychosocial support. As improvements in management have increased overall survival, quality of life has become a more important consideration in the treatment of pediatric sarcoma. The aims of this chapter are to provide a brief overview of the surgical approach to pediatric sarcoma and to describe the reconstruction of sarcoma defects, particularly for tumors of the extremities.

Osteosarcoma is an aggressive primary bone tumor that commonly presents in the long bones. Most cases occur in the absence of inherited syndromes or exposure to radiation. Associations with syndromes such as hereditary bilateral retinoblastoma, Li-Fraumeni syndrome, Bloom syndrome, Rothmund-Thomson syndrome, multiple exostoses, and Paget disease have been described.² The peak incidence of osteosarcoma is at 16 years of age, or during puberty, suggesting an association

with a high rate of bone growth. Approximately 20% of patients present with metastases, which are most frequently found in the lung.⁵ Osteosarcoma appears as both osteoblastic and osteolytic on plain radiographs, with an aggressive periosteal reaction; a triangle of immature bone at the edge of the bone cortex is described as a *Codman sign*. Skip metastases are found infrequently and should be identifiable on bone scan, CT, and MRI. The introduction of chemotherapy in conjunction with surgery in the 1970s as a treatment for presumed micrometastases led to the significant improvement in survival noted previously. Osteosarcoma is fairly resistant to radiotherapy.

Ewing sarcoma is part of a family of tumors that also includes primitive neuroectodermal tumors. The peak incidence is in the second decade of life.³ Although most Ewing sarcoma is found in bones, particularly in diaphyses, metaphyses, and the pelvis, soft tissue tumors have also been described. Approximately 25% of patients present with metastases most often found in the lungs, bone, and bone marrow.⁶ On plain radiographs, Ewing sarcoma has an onion-skin periosteal reaction and a moth-eaten appearance to the cortex. Soft tissue extension of the tumor often occurs early. Surgery, chemotherapy, and radiotherapy are all employed in the treatment of patients with Ewing sarcoma.

Rhabdomyosarcoma is the most common soft tissue sarcoma in children, and nearly two thirds of patients are younger than 10 years of age at presentation.⁴ The peak incidence is bimodal, occurring in children 2 to 6 years of age and 15 to 19 years of age.¹ Rhabdomyosarcoma can develop in any soft tissues of the body and is grouped according to anatomic sites; the genitourinary tract and the extremities are the most common locations. Fifteen to twenty percent of patients present with metastases that can be widespread.⁷ Surgery, chemotherapy, and radiotherapy are useful modalities in the management of rhabdomyosarcoma.

The other soft tissue sarcomas are grouped collectively and known as *nonrhabdomyosarcoma*. They are generally managed by surgical excision, and the use of radiotherapy and chemotherapy is inconsistent. The most common soft tissue sarcoma is *synovial sarcoma*, which is a rare tumor. It presents most often as a painless mass in the upper or lower extremities and has been associated with the chromosome translocation t(x;18)(p11;q11), in which segments of chromosome 18 and chromosome x have switched positions.

STAGING OF SARCOMAS

Two different staging systems are used for sarcomas.⁸ The Musculoskeletal Tumor Society, or the Enneking system, classifies benign musculoskeletal tumors as latent, active, or aggressive⁸ (Table 55-1). Malignant tumors are classified based on grade (low or high), whether the tumor is intra-compartmental or extracompartmental, and the presence of metastasis⁹ (Table 55-2). This system is useful for guiding surgical resection, because anatomic features of the tumors are included.

The American Joint Committee on Cancer (AJCC)¹⁰ employs the TNMG staging system for bone cancers. It is based on the size and depth of the primary tumor, the histologic grade, the regional lymph node status, and the presence of metastasis (Box 55-1). The Intergroup Rhabdomyo-

Table 55-1 Enneking Staging for Benign Musculoskeletal Tumors Based on Radiographic Characteristics of the Tumor Host Margin	
Stage	Description
Latent	Well-demarcated borders
Active	Indistinct borders
Aggressive	Indistinct borders

Table 55-2 Enneking Staging for Malignant Musculoskeletal Tumors Based on Surgical Grade, Local Extent, and Presence of Metastasis

Stage	Grade	Site	Metastasis
IA	Low (G1)	Intracompartmental (T1)	No metastasis (M0)
IB	Low (G1)	Extracompartmental (T2)	No metastasis (M0)
IIA	High (G2)	Intracompartmental (T1)	No metastasis (M0)
IIB	High (G2)	Extracompartmental (T2)	No metastasis (M0)
III	Any (G)	Any (T)	Regional or distant metastasis (M1)

Box 55-1 American Joint Committee on Cancer Staging System**T Stages of Bone Cancer**

TX: The primary tumor cannot be measured.

T0: No evidence of the tumor

T1: The tumor is 8 cm (about 3 inches) or less.

T2: The tumor is larger than 8 cm.

T3: The tumor is in more than one place on the same bone.

N Stages of Bone Cancer

N0: The cancer has not spread to the lymph nodes near the tumor.

N1: The cancer has spread to nearby lymph nodes.

M Stages of Bone Cancer

M0: The cancer has not spread anywhere outside of the bone or nearby lymph nodes.

M1: Distant metastasis (The cancer has spread.)

– M1a: The cancer has spread only to the lung.

– M1b: The cancer has spread to other sites (such as the brain and/or the liver).

Grades of Bone Cancer

G1-G2: Low grade

G3-G4: High grade

Stage Grouping

- Stage I: All stage I tumors are low grade and have not yet spread outside of the bone.
 - Stage IA: T1, N0, M0, G1-G2: The tumor is 8 cm or less.
 - Stage IB: T2 or T3, N0, M0, G1-G2: The tumor is either larger than 8 cm or it is in more than one place on the same bone.
- Stage II: Stage II tumors have not spread outside the bone (like stage I) but are high grade.
 - Stage IIA: T1, N0, M0, G3-G4: The tumor is 8 cm or less.
 - Stage IIB: T2, N0, M0, G3-G4: The tumor is larger than 8 cm.
- Stage III: T3, N0, M0, G3-G4: Stage III tumors have not spread outside the bone but are in more than one place on the same bone. They are high grade.
- Stage IV: Stage IV tumors have spread outside of the bone they started in. They can be any grade.
 - Stage IVA: Any T, N0, M1a, G1-G4: The tumor has spread to the lung.
 - Stage IVB: Any T, N1, any M, G1-G4 *or* any T, any N, M1b, G1-G4: The tumor has spread to nearby lymph nodes or to distant sites other than the lung (or both).

T = Features of the tumor (its size and whether it is in more than one spot on the bone); N = spread to lymph nodes; M = metastasis (spread) to distant organs; G = tumor grade.

Table 55-3 Intergroup Rhabdomyosarcoma Study Group Site-Modified Tumor, Metastasis, Number Staging

Stage	Sites	T	Size	N	M
1	Favorable	T1 or T2	a or b	N0 or N1 or Nx	M0
2	Unfavorable	T1 or T2	a	N0 or Nx	M0
3	Unfavorable	T1 or T2	a b	N1 N0 or N1 or Nx	M0 M0
4	All	T1 or T2	a or b	N0 or N1	M1

Definitions: Favorable sites = Orbit, head, and neck (excluding parameningeal), genitourinary (excluding bladder/prostate tumor), and biliary tract; unfavorable sites = bladder/prostate, extremity, cranial parameningeal, and other sites (including the trunk and retroperitoneum, but excluding biliary); T1 = confined to the anatomic site of origin, T2 = extension and/or fixation to the surrounding tissue; size a \leq 5 cm in diameter, b $>$ 5 cm in diameter; regional nodes N0 = regional nodes not clinically involved, N1 = regional nodes clinically involved by the neoplasm, Nx = clinical status of regional nodes unknown (especially sites that preclude lymph node evaluation); metastasis M0 = no distant metastasis, M1 = metastasis present. The pretreatment size is determined by external measurement using MRI or CT depending on the anatomic location. For less accessible primary sites, CT will be employed as a means of lymph node assessment. Metastatic sites will require some form of imaging but not histologic confirmation, except for bone marrow examination.

sarcoma Study Group modified an AJCC TNM system for soft tissue sarcomas to classify tumors based on site (favorable or unfavorable), whether the tumor is confined to the anatomic site of origin or extends into surrounding tissue, whether the tumor is greater than or less than 5 cm in diameter, the regional lymph node status, and the presence or absence of metastasis⁴ (Table 55-3).

DIAGNOSIS AND STAGING INVESTIGATIONS

Sarcomas present in a variable manner depending on the tissue of origin. Bone tumors often present with pain, swelling, and potentially a pathologic fracture, and soft tissue sarcomas typically present with swelling and a firm mass. Imaging is a key component of diagnosis and should take place before a surgical biopsy. Modalities, including radiography, MRI, and CT, help to define the tumor characteristics. For soft tissue lesions, ultrasound can be useful as a primary modality in younger patients in whom general anaesthesia may be required for MRI and judicious use of CT scans should be employed. Once the local imaging is complete, systemic imaging should be performed and may include further MRI to examine lymph node basins, CT scans of the chest and abdomen, whole-body bone scans, PET scans, and possibly bone marrow aspiration and biopsy for Ewing sarcoma and rhabdomyosarcoma. Bloodwork includes a CBC; an erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), both of which may be elevated with Ewing sarcoma, infectious causes, and lymphoma; and electrolytes, including calcium, magnesium, and phosphate. Serum alkaline phosphatase has been shown to correlate with 5-year, event-free survival in osteosarcoma.¹¹ Similarly, serum lactate dehydrogenase has prognostic value in osteosarcoma¹² and Ewing sarcoma.¹³

A tumor biopsy should be obtained with careful consideration of future requirements for surgical excision. The biopsy tract must be excised at the time of tumor resection. For tumors on the extremities, biopsies should be longitudinal along an extensile incision whenever possible (Fig. 55-1). Sampling multiple biopsy sites is not recommended. When these principles are not followed, the soft tissue reconstruction of the resulting defect may become unnecessarily complicated.

Fig. 55-1 A longitudinal biopsy incision line along an extensile incision.

Fig. 55-2 Low-grade infantile fibrosarcoma of the upper extremity.

SURGICAL MANAGEMENT

The primary guiding principle in the surgical management of pediatric sarcoma is oncologic safety. Complete resection of the tumor is factored into the staging and may indicate further treatment depending on the type of tumor. Secondary guiding principles include function, durability, complications, and appearance.

Four main types of excision exist for sarcomas⁹:

1. Intralesional excision
2. Marginal excision: The margins of excision are at the margin of the tumor.
3. Wide excision: The margins include a cuff of normal tissue around the tumor.
4. Radical excision: The entire compartment containing the tumor is excised.

The type of excision, or the surgical margin, required is determined by the characteristics of the tumor. For example, in a low-grade lesion such as an infantile fibrosarcoma in the upper extremity (Fig. 55-2), a marginal excision may be performed to maintain function of the limb. A clinical practice guideline developed for the surgical management of soft tissue sarcomas of the extremities recommends that the aim should be to achieve a clear margin, but in certain cases a close or microscopically positive margin may result.¹⁴ In such cases, radiotherapy may be employed as an adjuvant therapy. In high-grade osteosarcoma, the presence of a positive margin has been found to be the only predictor of local recurrence.¹⁵ In these patients, achieving a negative margin should be the aim of surgical management.

Neoadjuvant chemotherapy is commonly employed because of the theoretical increase in safety and the ease of obtaining a negative surgical margin. This rationale holds true for tumors that do not generate a matrix, such as Ewing sarcoma, because they predictably shrink with chemotherapy. However, this rationale does not necessarily apply for osteosarcoma and has not been clinically proven. In one study, surgical resection planning based on MRI changed after the neoadjuvant chemotherapy. The volume of the planned resection changed after chemotherapy but in an inconsistent manner. Some cases required less resection, and others required more than had originally been planned.¹⁶ Neoadjuvant chemotherapy targets potential systematic disease up front. Despite the surgical benefit of neoadjuvant chemotherapy, the known risk of increased wound-healing complications warrants further study.

Surgical Approach

Several key factors should be considered when planning a sarcoma excision:

- The most important factors are to ensure adequate margins based on the type of sarcoma and to determine which key structures can be preserved and which ones cannot.
- Joint involvement. If the bone on one side of a joint cannot be preserved, can the supporting structures (such as the joint capsule and ligamentous support) be preserved?
- Is the outlook for function reasonable, perhaps not normal but better than that offered by an amputation and prosthesis?
- The patient's and family's (for young children) preferences need to be considered.
- Can the joint be safely preserved but at the cost of joint stiffness? Rotationplasty may provide excellent knee function and convert an above-knee amputation to be a below-knee amputation.
- Is an unusual aesthetic appearance acceptable? As in all complex surgical procedures, the options must be carefully discussed with patients and their family.

Five main approaches are available for surgical reconstruction after excision of sarcomas of the extremities (Box 55-2). The first approach, soft tissue reconstruction only, is an option when the defect requires soft tissue cover only. The second, intercalary bony reconstruction, is applicable when an intercalary bony defect results from an excision that preserves the epiphysis. The third, joint resection and reconstruction, requires removal of a joint surface and reconstruction with bone (allograft and/or autograft, that is, fibular head) or with an endoprosthesis. The fourth approach is a rotationplasty in which the knee bony and supporting structures need to be removed. The knee joint is replaced by the ankle joint as the leg is shortened and rotated 180 degrees. It is an almost complete intercalary joint resection combined with a joint replacement. The "new knee" is powered by either the muscles of the calf (after a distal femoral tumor removal) or the muscles of the thigh (after a proximal tibial tumor removal). The fifth surgical approach is an amputation. Historically, this was the most common surgical procedure performed. However, currently, a limb-salvage surgery such as those listed in Box 55-2 is performed in nearly 90% of cases.¹⁷

Soft Tissue Cover Only

When only soft tissue cover is required after a tumor excision, the reconstructive options are numerous. The reconstructive ladder can be used fully. Closure can range from simple, direct approximation of adjacent, clear skin margins to free flap coverage of exposed bone (Fig. 55-3) and/or critical structures. In the patient shown in Fig. 55-3, about 50% of the cortex of the tibia had to be removed. A free latissimus dorsi muscle flap covered this readily, and an overlying split-thickness skin graft provided excellent contour.

Box 55-2 Approaches for Surgical Reconstruction After Tumor Excision of the Extremities

- I. Soft tissue reconstruction only
- II. Intercalary bony reconstruction
 - A. Bone only
 - 1. Allograft (cadaver bone)

Intercalary Excision and Reconstruction

An intercalary excision is indicated when an MRI shows the adjacent epiphysis is free of tumor and edema. Most children's high-grade bone tumors arise in the metadiaphysis and extend to the epiphysis over time. Although the physis is a relative barrier, it is only a matter of time until it is breached. If, after neoadjuvant chemotherapy, a preoperative MRI scan shows no epiphyseal edema, surgeons can be reassured that no microscopic tumor is present.¹⁸ An osteotomy can be performed on the epiphyseal side of the physis or directly through the physis if preoperative gradual epiphyseal lysis has been undertaken over 2 weeks with a frame (Fig. 55-4). Indications for this procedure are shown in Fig. 55-5.¹⁸

The reconstruction of an intercalary defect has historically included the use of allograft bone. With the development of microsurgical techniques, free vascularized fibula flaps have been incorporated into intercalary reconstruction with improved outcomes. The fibula provides a long segment of bone and possibly a cutaneous skin paddle if required. The intercalary defect can then be reconstructed with bone only or with bone and soft tissue. In a series comparing allograft alone and allograft with an internal vascularized fibula flap, patients receiving a vascularized fibula progressed to weight bearing faster and had fewer revisions but had a similar overall rate of complications.¹⁹ The fibula has been used as a single strut as well as a double-barreled construct. In a series of lower limb reconstruction after sarcoma resection in pediatric patients, the flaps united an average of 4 months after surgery, with patients able to bear weight an average of 6 months after surgery.²⁰ Hypertrophy was a continuing process, with greater than 30% hypertrophy occurring during the first 10 months in all patients, and a range of 30% to 200% hypertrophy after a mean of 38 months. A vascularized fibula flap was also used to salvage allograft nonunion, with an average of 10 months to bony union and 13 to 45 months to unrestricted activity of the limb.²¹ In allograft reconstruction alone, infection rates were reported to be 24% to 30%,²² whereas infection rates with a vascularized fibula flap were reported to be 10% to 14%.^{19,23-25} Reconstruction with a vascularized fibula flap can lead to excellent functional outcomes. In a series of pediatric patients with lower limb sarcoma, 56% returned to ambulation without an aid, and 39% were

Fig. 55-4 A distraction frame is in place to preserve the epiphysis.

Fig. 55-5 Indications for epiphyseal preservation in metaphyseal malignant bone tumors in children.

able to ambulate with an aid.²⁶ All children of school age were able to return to school, and 50% of children resumed sports.

Technical Considerations Regarding the Vascularized Fibula Flap A vascularized fibula flap is typically planned for the contralateral limb in lower extremity reconstruction to facilitate a two-team approach. A pedicled fibula flap has been used to reconstruct tibial defects that are positioned optimally; however, the inset of the bone can be difficult because of the restricted movement of the pedicle. The patient is positioned on two layers of sponge cushioning to minimize the potential for pressure-induced wounds. Venous thrombosis is rare in children, even in

oncology patients; thus anticoagulation is not employed. Separate operative setups are used to ensure oncologic safety with no contamination of the donor site with tumor, and full change of the surgical instruments is essential once the tumor is excised.

A fibula flap is dissected with a sterile tourniquet on the thigh. A lateral approach to the fibula is used for harvesting an osseous fibula flap, and a posterior approach is used for an osteocutaneous fibula flap, as described in the literature.²⁷ If no skin paddle is required, a longitudinal incision along the posterior border of the fibula is marked, leaving 6 cm of bone proximally and distally in adolescents and as little as 4 cm in younger children. Rarely, a longer length of bone is required, and a syndesmotic screw is placed between the distal fibula and the tibia to ensure joint stability. The bone to be used in the flap is oriented distally to allow maximal length of the pedicle. Even if the amount of bone required for the reconstruction is less than the available length, removing the proximal bone facilitates the dissection of the full length of the pedicle. If a skin paddle is required, the skin is oriented on the distal aspect of the available fibula, and a Doppler probe is used to identify perforating vessels (Fig. 55-6).

Fig. 55-6 This case shows the role of an osteocutaneous fibula flap for reconstruction after excision of an extensive tumor of the tibia. **A**, A reoperative radiograph of a tumor amenable to intercalary resection. **B**, Intraoperative planning involved measuring the length of fibula required. **C**, The tumor was excised, and the defect was extensive. **D**, An osteocutaneous fibula flap was marked.

Fig. 55-6, cont'd **E**, The flap was harvested. The vascular pattern to the skin component is shown. **F**, Surgical transfer of the flap was complete. Suction drains were placed in the donor site and the recipient site. **G**, Postoperative venous congestion led to loss of most of the cutaneous portion of the flap despite the use of leech therapy. **H**, The patient is shown postoperatively after interval healing with skin grafting of debrided necrotic skin of the cutaneous component of the osteocutaneous flap. **I**, A postoperative radiograph of the reconstructed tibia with vascularized fibula. Solid bony union of the fibula is evident proximally and distally.

Fig. 55-7 A vascularized fibula provides rapid, solid union, whereas an allograft provides immediate strength. **A**, Intraoperative view of a composite reconstruction with allograft and vascularized autograft. Allograft is stabilized with a plate, and the fibula is underneath it, out of view. A microscope is in place for repairing the peroneal vessels. **B**, A postoperative radiograph of a femoral reconstruction using a large allograft fixed by plates and screws for strength and a vascularized fibula for rapid healing.

The fibula is inset with the orthopedic oncologist present. If the remaining bone is of adequate length, intussusception of the fibula into the remaining bone aids in preventing nonunion.

In patients in whom an allograft is also required to provide early support, a composite reconstruction may be helpful, as popularized by Ceruso et al.²⁸ The fibula is inset in a generous, wide posteromedial slot created in the allograft. It is fixated with long plates but with a minimal number of screws, without violating either the allograft or the autograft, to create a stable construct (Fig. 55-7).

Recipient vessels are identified during the tumor resection. End-to-end anastomoses are preferable, if possible; however, end-to-side anastomoses are often used in wide resections in which few vessels of adequate caliber remain in the operative field.

Postoperatively, patients are placed on a caffeine-free diet. A soft, bulky dressing, occasionally with a splint depending on the proximity of the dissection to a joint, is placed on the reconstructed extremity with adequate visualization of the distal digits to monitor vascularity. With the known high rate of complications with sarcoma surgery, patients are monitored closely in the hospital during their average hospital stay of 15 days.²⁶ Progressing to healing as quickly as possible is important to resume chemotherapy, typically about 2 weeks postoperatively (Fig. 55-8).

Fig. 55-8 This patient had malignant bone tumors amenable to intercalary resection and reconstruction with a vascularized fibula flap. **A**, Preoperative MRI showed a tumor of the distal tibia. **B**, An intraoperative view after the tumor was dissected free and ready for removal. **C**, A postoperative radiograph showed the transferred contralateral fibula in place. **D**, An intraoperative view at the completion of the osteocutaneous fibula flap transfer. **E**, A radiograph obtained 2 years after the transfer shows excellent bony healing proximally and distally and interval hypertrophy of the transferred fibula.

Joint Resection and Reconstruction

When tumor has involved the epiphysis, most surgeons would resect at least that side of the joint (intracapsular resection). In this situation, when the extracapsular structures can be preserved, a joint reconstruction using bone can be of considerable benefit. Cadaver allograft joint reconstruction has not been reliable or durable. However, the fibula with its head can be transferred as living bone and living joint by microvascular techniques. Thus, for example in young children, resection of the femoral or humeral head can be reconstructed with an osteoarticular fibular free flap (Fig. 55-9). The revascularization has been described based on the peroneal vessels, as discussed earlier in the chapter (see Fig. 55-7), or based on the anterior tibial vessels.²⁹ Over time the fibular head will remodel to some degree to mimic the joint surface of the reconstructed joint. In the patient shown in Fig. 55-10, the ankle mortise was reconstructed with the fibular head, preserving function. This form of reconstruction is not commonly feasible because of oncologic considerations. Oncologic safety remains the priority. If a joint is devascularized as a result of tumor resection, salvage is not possible, and future growth and limb-length discrepancies should be considered when planning the reconstruction. In growing children, this anticipated growth discrepancy can be considerable and functionally limiting, particularly in the lower extremity. They may in time require surgical intervention as opposed to a simple shoe raise. Such surgical options include contralateral epiphyseodesis, acute contralateral shortening, and ipsilateral leg lengthening.

Fig. 55-9 This 1-year-old child favored his left hip during attempted walking. The imaging workup demonstrated a Ewing sarcoma of the femoral head. This was confirmed by an open biopsy specimen. The tumor and femoral head were resected and the femur reconstructed with a free vascularized fibula, including the fibular head. **A**, A preoperative MRI showed the bone tumor of the left femur. **B**, The bony defect after tumor excision. The acetabulum was exposed. **C**, The fibula was positioned, with soft tissue reconstruction proximally and plate and screw fixation distally. **D-F**, The patient is shown 2 years after surgery, chemotherapy, and a rehabilitation program. He is weight bearing and pain free with adequate mobility. Radiographs show hypertrophy of the femur and remodeling of the new femoral head.

Fig. 55-10 This patient underwent a microvascular transfer of the fibular metaphysis, growth plate, and epiphysis for reconstruction of the distal fibula at the distal tibia-fibula joint after resection for osteogenic sarcoma. **A**, The appearance of the leg before tumor excision. The biopsy incision was marked for excision. **B**, A plain radiograph showed an osteogenic sarcoma of the distal fibula. **C**, An intraoperative view of the defect of fibula after the tumor excision. The open joint was without the distal fibula. **D**, Reconstruction of the distal fibula. The proximal fibula with its growth plate and epiphysis was removed, reversed, and revascularized with bone and the peroneal and lateral geniculate vessels. **E**, A postoperative radiograph showed remodeling of the fibular head to create a stable ankle mortise. **F-H**, In a late follow-up, the patient has satisfactory contour and normal dorsiflexion and plantar flexion.

Endoprosthetic reconstruction and rotationplasty are the most common options for joint resection in children. Some tumors are amenable only to rotationplasty, because they are large and limb salvage would not be oncologically safe. However, often, families have to make a choice based largely on how they value appearance versus durability. Although a vascularized fibula flap can salvage some joints, oncologic safety remains the priority and may prohibit this form of reconstruction.

Reconstruction With an Endoprosthesis

An endoprosthetic reconstruction is a viable option for reconstruction in patients who require resection of a joint. It can be particularly helpful for joint reconstruction in patients who prefer limb salvage and are content not to attempt high-impact activities lifelong. They should be prepared for potentially multiple revisions during their lifetime because of anticipated aseptic loosening and unanticipated complications such as infection and mechanical implant failure.

Although the use of a prosthesis can result in rapid mobilization, the hardware requires coverage with well-vascularized tissue for success. The stability of an endoprosthesis around the knee is straightforward, because the implants are constrained by a hinge. However, hemiarthroplasty using a prosthesis at the shoulder, proximal femur, and hip is difficult. It requires special consideration particularly if a wide or radical resection has removed the normally stabilizing soft tissue around the joints. Survival of an endoprosthesis has been reported to be 86%, 80%, and 69% at 3, 5, and 10 years, respectively.³⁰

Pediatric patients are more likely than adults to require revision procedures in the future in part because of device failure.² Some endoprostheses have been developed to be expandable over time to account for growth and the challenges of managing limb-length discrepancies. Most are now lengthened in a closed manner, thus limiting the number of open procedures required. However, these devices are weaker and mechanically more vulnerable than solid implants. An alternative option for endoprosthetic reconstruction in children is to use custom-sized but non-expandable implants that are solid and presumably less likely to fail mechanically. Limb length then can be managed by methods mentioned previously.

An endoprosthesis requires coverage with well-vascularized tissue to minimize infection risk, and soft tissue coverage is best undertaken at the initial surgery³¹ (Fig. 55-11). The proximal femur is deep and often has sufficient endogenous soft tissue coverage even in a wide tumor resection. The shoulder and the knee may require additional soft tissue coverage. Around the shoulder, local muscles such as the latissimus dorsi can be used, and around the knee, the medial gastrocnemius is a good option. If local muscles have been resected, free tissue transfer is required to ensure coverage of the prosthesis.

Rotationplasty

A rotationplasty is an alternative to an endoprosthetic reconstruction where the joint has been resected. This procedure is most often performed at the level of the knee for distal femur and proximal tibia tumor resections. It involves resecting a segment of the limb, including the entire knee joint, turning the remaining lower leg and ankle joint 180 degrees, and reconnecting the tibia to the proximal femur.³²⁻³⁵ Thus the ankle becomes the new knee joint³⁶ (Fig. 55-12). No joint prosthesis is required, and patients are often able to adapt remarkably well function-

Fig. 55-11 Endoprosthesis reconstruction requires well-vascularized coverage. **A**, A preoperative radiograph showed a malignant bone tumor of the proximal tibia, necessitating joint removal. **B**, With the endoprosthesis in place, the gastrocnemius muscle was mobilized and transposed to cover the prosthetic device. **C**, The muscle flap was transferred and sutured in place. **D**, A postoperative radiograph shows the endoprosthesis well integrated into the femur proximally and the tibia distally.

ally³⁷⁻⁴⁰ (Fig. 55-13). If the vessels are safe to dissect, they are coiled, along with the sciatic nerve and its branches. To prevent arterial kinking or clotting, and if vascular supply is close to the tumor, the femoral artery and vein are resected and anastomosed to the remaining distal popliteal or posterior tibial artery and vein by the microsurgical team. Large vessel clamps are required to maintain proximal and distal control of the vessels before anastomosis. Preservation and coiling of the saphenous vein may help to prevent outflow insufficiency in the event of deep venous thrombosis. The tibial nerve is left intact to power the new knee into extension. Involvement of the tibial nerve by tumor had been regarded as a contraindication to rotationplasty. However, it is possible to resect a segment of the nerve with the tumor and coapt the clear end to successfully restore function.

Fig. 55-12 Rotationplasty for tumors of the distal femur or proximal tibia/fibula when knee joint preservation is not possible. The ankle is preserved and rotated 180 degrees. With limb shortening, it becomes the new knee joint. **A**, A preoperative MRI showed tumor invading the distal femur, precluding joint preservation. **B**, Surgical planning for a Van Nes rotationplasty. The planned incisions on the proximal thigh and leg included the biopsy site. **C**, The tumor was excised. The distal leg will be rotated 180 degrees, with the tibia connected to the femur by a plate. The sciatic nerve is intact and will be curled in continuity at the site of union. **D**, A microscope was moved into the field for repair of the femoral artery and vein to the posterior tibial artery and vein. **E**, The appearance after revascularization of the leg.

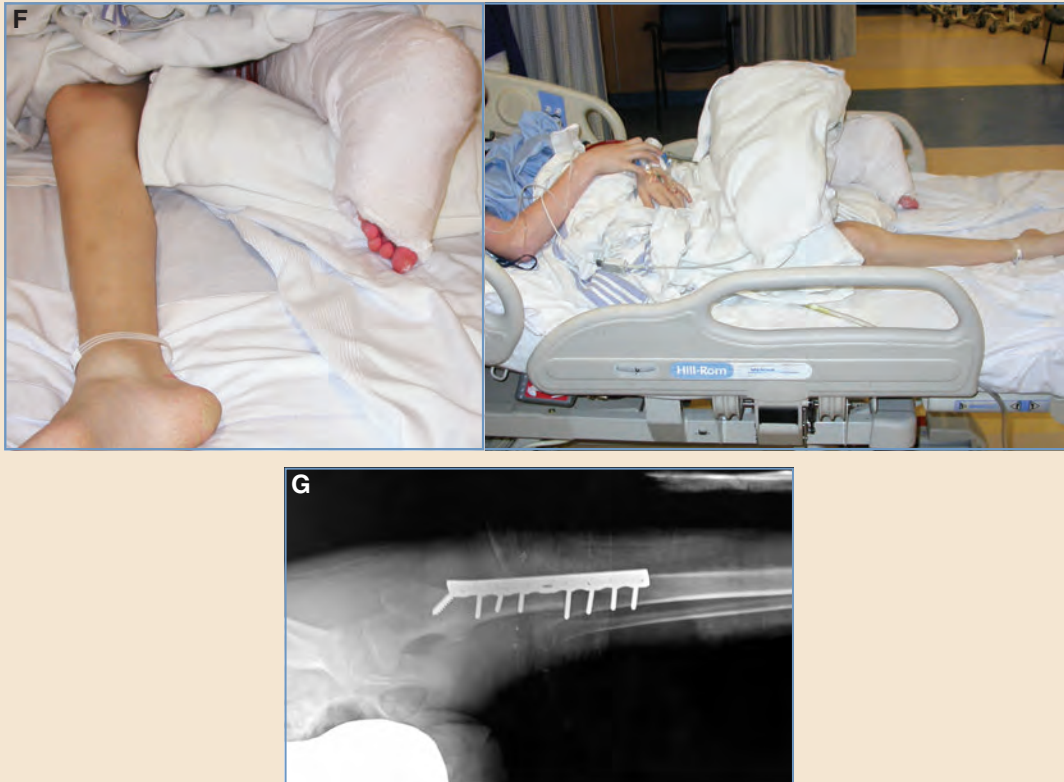

Fig. 55-12, cont'd F, The postoperative position shows rotation of leg. G, A radiograph of the femoral-tibial plating.

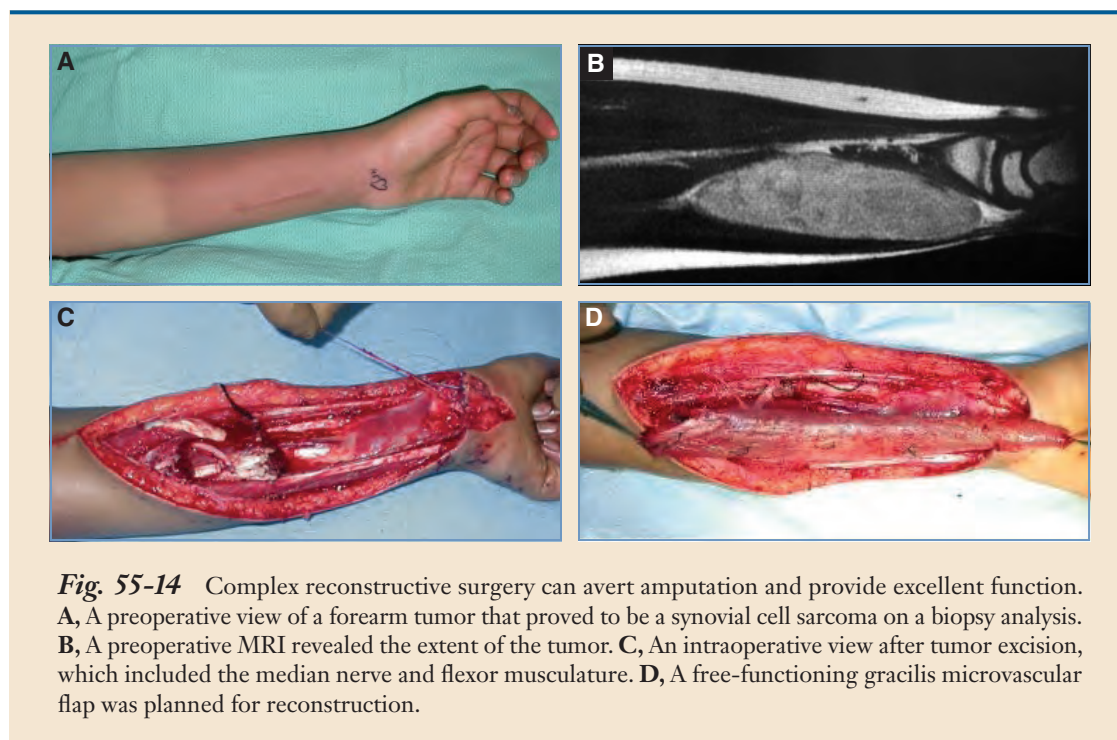

Fig. 55-13 Rotationplasty provides an excellent functional reconstruction where the knee joint must be resected. This patient underwent rotationplasty and pursued kayaking as a competitive sport. This woman was the flag bearer for Team Canada at the 2015 International Canoe Federation World Championships, where she finished seventh. She might represent Canada in the 2016 Paralympic Games also.

Controlling for leg length is an important consideration for both endoprosthesis reconstruction and rotationplasty. In a rotationplasty, the length of the reconstructed femur is typically left longer than that of the contralateral femur in growing children. This will account for future discrepant growth and gradually match the center of knee rotation by skeletal maturity. Procedures to address limb-length discrepancy include limb lengthening using distraction osteogenesis, epiphysiodesis of the long limb to limit growth, and limb shortening of the longer limb.

Amputation

In certain cases such as tumors around the ankle or foot, below-knee or more distal amputation is often the optimal procedure. For large tumors at any site, if a negative resection necessitates sacrifice of multiple critical structures, salvage may not be a viable option. Limb salvage is only reasonable if the neurovascular status of the limb is not compromised, and the function will be better than that of a prosthesis. Reconstructive techniques such as vascular and nerve grafting, nerve transfers, and functioning muscle transplantation (Fig. 55-14) continue to allow us to improve our limb-salvage abilities and avert amputation. Where amputation is necessary, creating a durable stump for future mobility and preventing neuroma formation are critical. Patient-reported functional outcome differs little between endoprosthetic reconstruction, rotationplasty, and amputation.⁴¹ However, this may not reflect patient and family preferences.

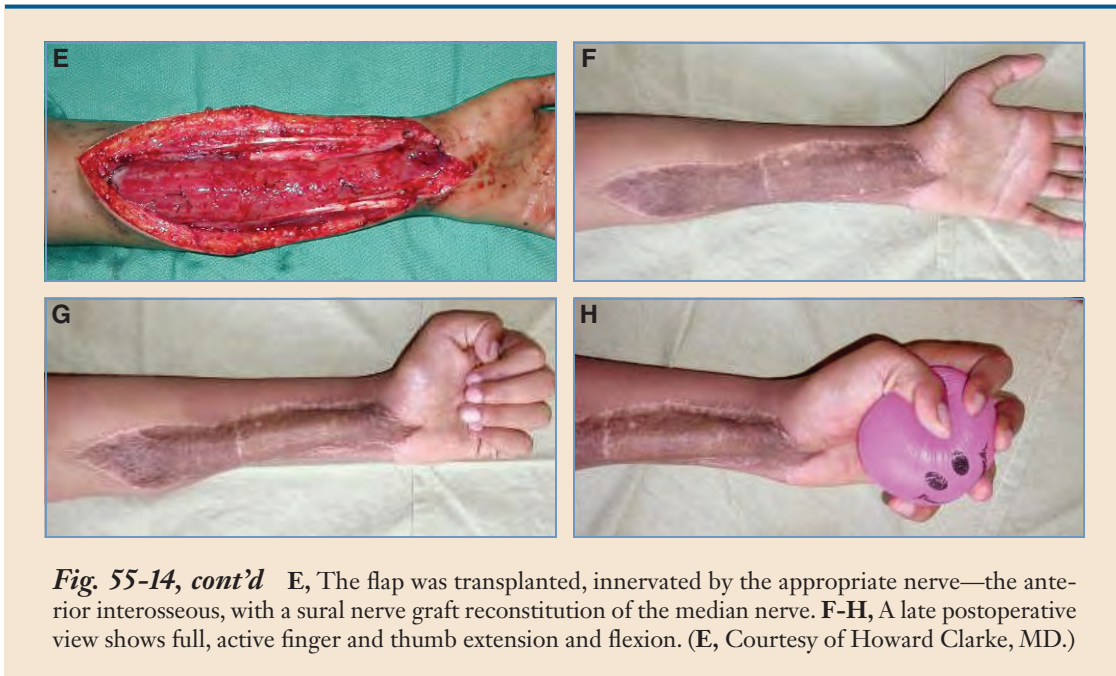

Fig. 55-14, cont'd **E**, The flap was transplanted, innervated by the appropriate nerve—the anterior interosseous, with a sural nerve graft reconstitution of the median nerve. **F-H**, A late postoperative view shows full, active finger and thumb extension and flexion. (**E**, Courtesy of Howard Clarke, MD.)

CONCLUSION

Sarcoma reconstruction in pediatric patients requires applying the principles of oncologic safety, optimizing function, and optimizing quality of life. As adjuvant therapies have improved survival, surgical techniques continue to evolve to minimize the morbidity of surgical resection. The main types of resection of tumors of the extremities include intercalary resection with vascularized bony reconstruction, joint resection with an endoprosthesis, joint resection with rotationplasty, and amputation. Free tissue transfer has significantly improved the ability to perform limb salvage surgery with good functional outcomes. Accounting for future growth of the child is an important challenge. Striving for the best possible functional outcome with the least amount of treatment burden, recognizing the potentially large number of procedures patients often require, has become the goal of reconstructive surgeons on the multidisciplinary team.

KEY POINTS

- Osteosarcoma, Ewing sarcoma, and rhabdomyosarcoma are the most common sarcomas in children.
- Tissue diagnosis requires a core biopsy that should be planned carefully along an extensile incision, with future resection in mind.
- Wide resection should be the primary surgical goal for aggressive tumors; in low-grade lesions, consideration of function may influence the excision margins.
- There are five approaches for surgical reconstruction after tumor excision:
 1. Soft tissue cover only
 2. Intercalary resection and reconstruction
 3. Joint resection and reconstruction
 4. Rotationplasty
 5. Amputation
- Vascularized fibula flaps, nerve reconstruction, and microvascular reconstruction techniques have increased the ability to salvage limbs and prevent amputation.
- The goals of treatment should be to obtain negative margins on resection and to maximize functional outcomes, while keeping the patient's and family's preferences in mind.

Pediatric Lower Extremity Reconstruction

*Mary C. Snyder • Mark W. Kiehn • Steve J. Kempton
Michael L. Bentz*

he lower extremity presents a unique challenge to reconstructive surgeons because of its weight-bearing requirement, dependent position, subcutaneous location of the tibia, paucity of distal soft tissue, and inherent healing difficulties. As with many surgical advances, lower extremity reconstruction has significantly evolved as a result of wartime experiences, contributions of orthopedic and plastic surgeons, and advances in surgical techniques and related technologies.¹ Advances in pedicled and microsurgical flap techniques have revolutionized soft tissue reconstitution for lower extremity reconstruction.² Orthopedic advances in fixation techniques and distraction osteogenesis have also helped to expand the number of patients who are candidates for lower extremity salvage after cancer treatment and trauma.³ As the means for restoring form and function improve, indications and standards for reconstruction change. This chapter explores the issues that reconstructive surgeons face and the techniques and principles available to address these challenges.

SPECIAL CONSIDERATIONS FOR PEDIATRIC PATIENTS

Similar to reconstructive problems in adults, most reconstructive problems in children result from traumatic injuries. Congenital anomalies and defects from tumor extirpation are also encountered.^{4,7}

Pediatric patients with lower extremity defects present additional challenges, compared with adults with similar injuries.⁴ Pediatric patients and their parents may have more fear and anxiety than adult patients. Wound care and surgical and anesthetic techniques should be modified to reduce this apprehension. Examination and dressing changes may require sedation or general

anesthesia. Limited comprehension and an inability to comply with treatment recommendations further compound the difficulties of treating younger patients. However, children tend to tolerate prolonged immobilization well and generally rehabilitate more easily than adults.^{8,9} This allows a more liberal use of casts, splints, and bulky dressings, which are often used to protect surgical sites even in the absence of skeletal and ligament injury.

Pain is managed using a multimodal approach for pediatric patients with lower extremity injury. The three types of pain that often occur are (1) acute postoperative pain, (2) persistent long-term nociceptive pain, and (3) complex neuropathic pain. The rehabilitative process should include a combination of multiple pharmacologic and nonpharmacologic measures to appropriately manage pain from traumatic or surgical insult.¹⁰

A pediatric reconstructive surgeon must appreciate the dynamic nature of the structures requiring reconstruction. In patients with substantial growth potential, the impact of injury and surgeries on development must be considered. Reconstructive options that accomplish treatment goals with the least impact on development should be chosen.

EPIDEMIOLOGY

Recent statistics from the Centers for Disease Control and Prevention showed that trauma continues to be the leading cause of death among children 1 to 18 years of age, with motor vehicle accidents being a prominent factor.¹¹ An epidemiologic review of multiply injured children found that infants, toddlers, and preschoolers are most commonly injured as motor vehicle passengers, whereas children 6 to 17 years of age are more often injured as pedestrians or cyclists.¹² Traumas of the lower extremity and head are the most common types of injuries in pediatric patients with multiple injuries. Lower extremity trauma in children is also seen after all-terrain vehicle accidents,¹³ lawn mower injuries,^{8,9} and gunshot wounds.¹³

The National Cancer Institute reports that cancer incidence rates for children 0 to 14 years of age from 2008 to 2012 were 1.1 per 100,000 for soft tissues and 0.8 per 100,000 for bones and joints.¹⁴ Defects that result from excision of tumors affecting the lower extremities make up a small but challenging subset of all cases requiring lower extremity reconstruction. Combinations of soft tissue, vascular, skeletal, and neural defects, with the possibility of postoperative radiotherapy, create unique challenges in caring for these patients.

EVALUATING A TRAUMATIZED LOWER EXTREMITY

The initial management of pediatric patients with lower extremity trauma follows the Advanced Trauma Life Support guidelines established by the American College of Surgeons. Patients are assessed and treated in a systematic manner that ensures that other life-threatening injuries are detected. This prevents the treating team from being distracted by injuries that are perhaps more graphic yet less lethal than others of a more subtle nature. The initial care of a traumatized extremity may be deferred until a patient is stabilized. The evaluation consists of carefully assessing vascular, sensory, motor, and skeletal integrity and determining the extent and location of associated soft tissue defects. In many patients, sedation or even general anesthesia may be necessary for some parts of the examination. Surgeons must determine whether patients have significant bleeding or ischemia of the traumatized areas, because these issues require urgent intervention. Ischemia in the presence of a displaced fracture or a dislocation may be alleviated through reduction alone. For this reason, reduction should be performed before vascular studies and surgical exploration. Appropriate radiographic studies complement the physical examination and reveal the extent of underlying skeletal injury.

A decision to perform reconstruction or completion amputation is based on the initial viability of the tissues and the potential long-term functional outcome. In the acute setting, this decision-making can be challenging, because the extent of injury is often difficult to appreciate. For pediatric lower extremity injuries, the indications for attempted limb salvage are much more liberal than those for adults, and some authors advocate attempts at reconstruction in nearly all cases.^{4,15} Injury assessment tools have been developed to aid in decision-making. The Limb Salvage Index (Table 56-1) takes into account the degree of vascular, neural, skeletal, and soft tissue injury and warm ischemia time before presentation.¹⁶ The Mangled Extremity Severity Score is another scale of objective clinical findings that is frequently used for adults to predict the potential for salvage of a traumatized lower extremity¹⁷ (Table 56-2). In a retrospective application of this score to a pediatric trauma population, it was an accurate predictor of prognosis in 93% of injured legs.¹⁸

Early plastic surgery consultation may facilitate decision-making and earlier wound closure for patients who have lower extremity injuries with significant soft tissue defects.¹⁹ Lower extremity trauma can involve skeletal, neural, vascular, and soft tissue injuries and is best managed through a multidisciplinary approach. Restoring vascular integrity is the most important initial aspect of management after a patient is stabilized. This may involve reduction of displaced fractures or dislocations, vascular repair, or grafting. The tolerance for ischemia varies with the level of injury, the types of tissues involved, and whether the ischemia is warm or cold. Wound debridement and closure, when possible, and temporary or definitive fracture stabilization are also

Table 56-1 Limb Salvage Index

Area Assessed	Score*
Artery	0 = Contusion, palpable pulses 1 = Two-vessel leg occlusion 2 = Proximal vessel occlusion (no runoff)
Nerve	0 = Stretch injury, clean distal cut 1 = Partial transaction 2 = Complete or sciatic-level injury
Bone	0 = Closed fracture, open simple joint 1 = Multiple (>3) or open fracture 2 = Bone loss >3 cm
Skin	0 = Clean laceration 1 = Contaminated, delayed closure
Muscle	0 = Laceration, single compartment 1 = Laceration, two compartments 2 = Crush injury
Deep vein	0 = Contusion, partial laceration 1 = Complete laceration or avulsion
Warm ischemia	0 = <6 hours 1 = 6 to 9 hours 2 = 9 to 12 hours 3 = 12 to 15 hours 4 = >15 hours

*Scores greater than 6 indicate a poor prognosis for limb salvage.

Table 56-2 Mangled Extremity Severity Score

Area Assessed	Score*
Skeletal/soft tissue injury	1 = Low-energy (simple fracture, gunshot wound, stab) 2 = Medium-energy (open fracture, dislocation) 3 = High-energy (crush, high-velocity gunshot wound) 4 = Very high-energy (contaminated, open fracture)
Limb ischemia	1 = Pulse deficit, normal perfusion 2 = Pulselessness 3 = Cold, insensate (*score doubles with ischemia >6 hours)
Shock	0 = Systolic blood pressure >90 mm Hg 1 = Transient hypotension 2 = Persistent hypotension
Age	0 = <30 years 1 = 30 to 50 years 2 = >50 years

*Scores greater than 7 indicate a poor prognosis for limb salvage.

generally performed at the initial presentation. With more extensive injuries, repeated debridement is often required. Such debridement should remove clearly devitalized and contaminating material but also should preserve important functional elements when possible. Once the wound has stabilized, definitive soft tissue coverage, skeletal stabilization, and bone reconstruction can be performed.^{13,20} The preferred timing of soft tissue coverage depends on the nature of the injury. Soft tissue coverage within 7 to 15 days of injury is generally preferred.¹³ This timing has been associated with reduced infection rates in adults and generally allows technically easier surgery and lower complication rates.²¹⁻²³

HEALING BY SECONDARY INTENTION

Negative Pressure Wound Therapy

Delays in soft tissue coverage may be necessary because of factors associated with a patient's general health or because of wound-related factors. In patients with substantial contamination or extensive soft tissue injury, the need for repeated wound debridement and stabilization may prevent definitive wound coverage during the early time frame.²⁴ In these cases, lower extremity wounds can be temporized with daily wet-to-dry dressing changes or with the use of negative pressure wound therapy (NPWT). NPWT, in contrast to more traditional wound care, allows a substantial decrease in dressing changes, resulting in decreased patient pain and apprehension and the need for less sedation.²⁵ NPWT may decrease the rate of revision amputation and the need for free flap coverage; however, this may be at the expense of a longer hospitalization time.²⁶ Once the wound is debrided, generating healthy granulation tissue and adequate tissue perfusion, the NPWT can be discontinued, and either skin grafting or flap coverage can be performed, depending on the reconstructive plan.²⁶

Dermal Regeneration Templates

Dermal regeneration templates are increasingly used for coverage of lower extremity defects to minimize donor-site morbidity in pediatric patients.²⁷ It provides immediate wound coverage,

Fig. 56-1 **A**, This patient had a left lower extremity giant nevus extending from the middle portion of the leg to the proximal aspect of the foot. **B**, The affected skin was excised to unaffected deep tissues. Integra was immediately applied and left in place for 3 weeks. The outer silicone sheet was then removed, and split-thickness skin grafting was performed (not shown). **C-E**, The patient is shown post-operatively in an anterior view and a lateral view in dorsiflexion and plantar flexion.

even with exposed bone or tendon, when a nonautologous option is promptly required. Integra is a bilaminar dermal regeneration template comprising an outer silicone epidermis-like protection layer and a deep layer of bovine collagen and glycosaminoglycans created from shark chondroitin-6-sulfate. Once placed, Integra becomes a template for growth factors and cellular ingrowth where survival is not dependent on imbibition or inosculation.²⁷ Routine use entails placement of Integra on a clean wound bed, which becomes vascularized with cellular ingrowth over a period of 2 to 3 weeks. The silicone sheet may then be removed, and the wound is grafted or secondary intention healing is allowed to continue, potentially preventing the need for free flap coverage.²⁷ The use of dermal regeneration templates should be considered an additional tool in the reconstructive armamentarium, particularly in the difficult distal third of the leg and in clinical settings when free flap surgery may not be available (Fig. 56-1).

ANATOMIC BASIS AND SURGICAL TECHNIQUES OF LOWER EXTREMITY FLAPS

The lower extremity can be divided conceptually into regions with relatively distinct anatomic characteristics and functional properties. These areas have different reconstruction requirements and different amounts of local tissue available to lend to these efforts. The lower extremity can be considered both a donor and recipient for pedicled and microsurgically transferred flaps. Surgeons should understand the anatomy to appreciate the options and limitations of local tissue alternatives for reconstructing defects. Appreciating the physiology of the affected area helps to guide surgeons in re-creating or approximating the functional components that require repair or replacement. With the variety of techniques available, the goals of reconstruction have shifted from simply healing open wounds and eradicating infection to providing reconstructions that are both functional and aesthetic. In this section, flap options from various regions of the lower extremity are discussed. The characteristics of the flaps and their uses for reconstruction are presented.

Thigh

The thigh contains an abundance of well-vascularized soft tissue relative to the amount of bone. A number of flaps can be raised from the skin, fascia, and muscle of this region as composite flaps or isolated components and as pedicled or microsurgical flaps, depending on the reconstructive needs (Fig. 56-2).

Fig. 56-2 Flap options for reconstructing the proximal thigh and groin.

Fig. 56-3 Arterial anatomy of the lower extremity.

The skin of the thigh presents several flap choices that can be elevated as fasciocutaneous flaps. An anterolateral thigh flap is supplied by perforators from the descending branch of the lateral circumflex femoral vessels (Fig. 56-3). Most perforators are found near the central third of a line drawn from the anterior superior iliac spine to the superolateral aspect of the patella.²⁸ This line corresponds to the intramuscular septum between the vastus lateralis and the rectus femoris muscles (Fig. 56-4). Although this flap was initially described as supported by septocutaneous perforators, up to 90% of the perforators pass through the vastus lateralis muscle to supply the skin.²⁹ The skin is richly supplied through a subdermal plexus, allowing a flap to be thinned once the perforator vessels are identified and protected. A cuff of fat is left around the perforator, and the flap can be thinned to 3 to 4 mm in thickness.³⁰ Thus the flap is an option for reconstructions requiring thin flaps, even in patients with greater degrees of subcutaneous adipose tissue. An anterolateral thigh flap can be harvested as a fascial flap or raised in conjunction with the vastus lateralis muscle, the tensor fascia lata, and/or the fascia lata, depending on the reconstructive

Fig. 56-4 Anatomy of the anterior thigh. This area derives vascularity primarily from deep femoral artery branches and offers a wide variety of muscle, skin, and fascia flaps.

needs³¹ (Fig. 56-5). The flap can be raised with antegrade flow through a proximal pedicle for coverage of the abdomen,³² groin, and proximal thigh or with retrograde flow through a distally based pedicle with vascular connections to the lateral superior genicular or deep femoral vessels in the distal thigh for coverage of the knee, popliteal fossa, and upper aspect of the leg³³ (see Fig. 56-3). The patellar tendon can be reconstructed simultaneously with soft tissue coverage by including fascia lata with the flap.³³ In designing these distally based flaps, surgeons must assess the adequacy of the distal vascular communications when previous surgery or trauma might have compromised them.

A lateral thigh flap is based on perforators of the deep femoral artery and may be based proximally for coverage of trochanteric and ischial wounds or distally for inferior thigh and knee defects. A medial thigh flap is based on the anterior septocutaneous branch of the superficial femoral artery in the midthigh overlying the sartorius and the rectus femoris. Applications include perineal wounds, genitourinary reconstruction, and postburn groin contractures.³⁴

The muscles of the thigh comprise a substantial amount of soft tissue divided into three fascial compartments (Box 56-1; see Fig. 56-4).

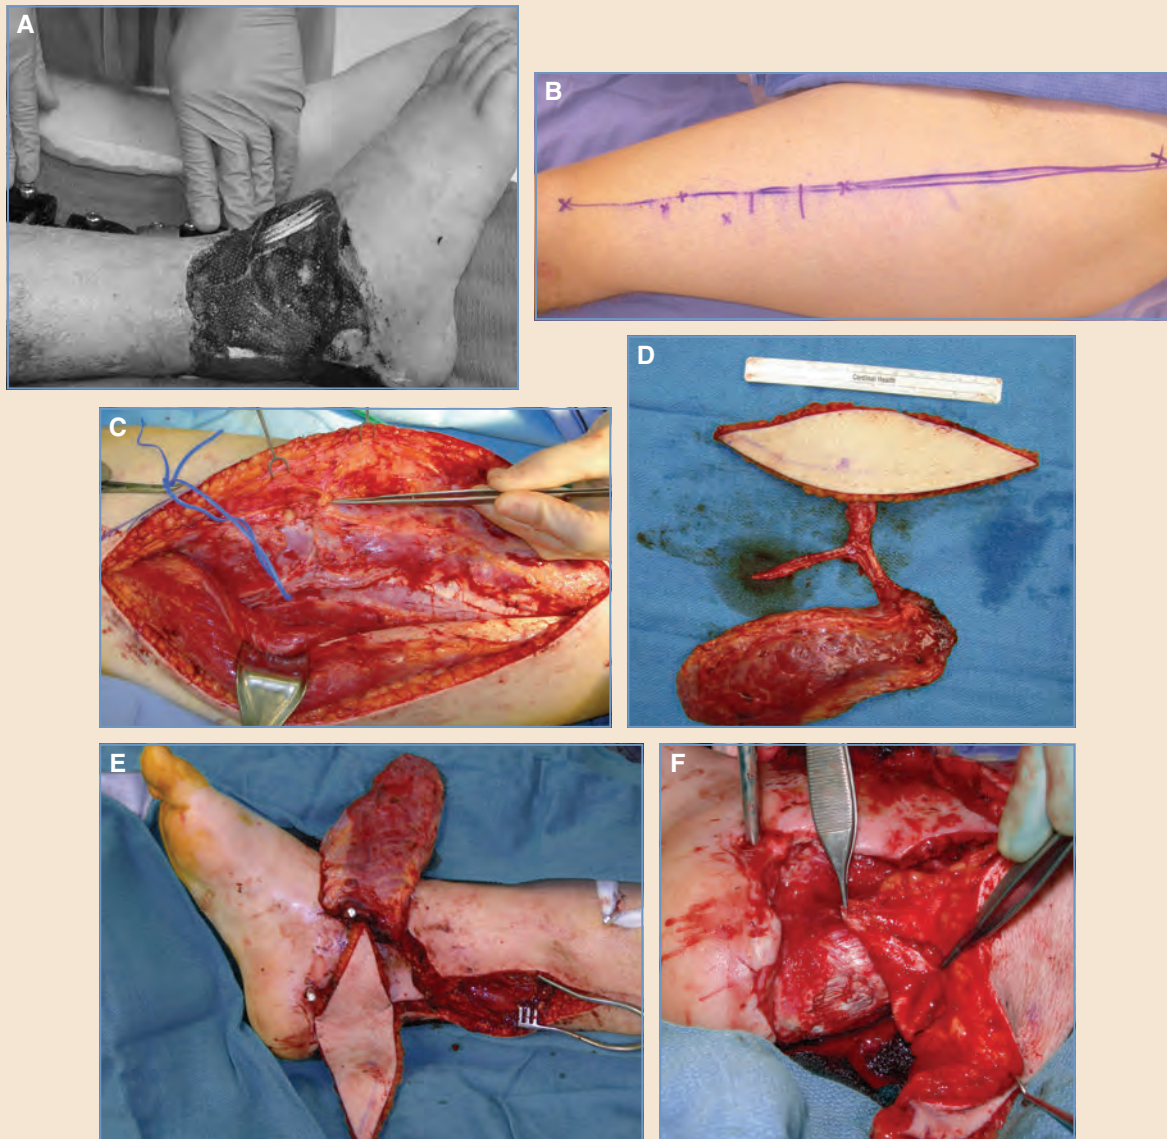

Fig. 56-5 **A**, This patient had an open dislocation of the right ankle with loss of soft tissue coverage. The wound was nearly circumferential. The ankle joint was stabilized with an external fixator. **B**, The intermuscular septum between the vastus lateralis and rectus femoris muscles of the left thigh was marked. Cutaneous vessels were identified with a handheld Doppler probe and their positions marked. **C**, The descending branch of the lateral circumflex femoral artery was identified between the vastus lateralis and rectus femoris muscles. The vessel penetrated the vastus lateralis muscle as it coursed distally in the thigh. A branch that coursed to the skin was identified within the intermuscular septum. **D**, An anterolateral thigh flap and a partial vastus lateralis flap were raised from the left thigh with a common pedicle (the descending branch of the lateral circumflex femoral artery and vein). Generous pedicle length is a useful feature of these flaps. **E**, Anastomosis to the posterior tibial vessels was performed, and a flap inset was planned. **F**, A segment of fascia lata included on the deep surface of the skin paddle was used as a vascularized fascia flap for reinforcement of the compromised Achilles tendon.

- Semitendinosus
- Semimembranosus

The vascular supply to the muscles of the thigh is primarily derived from branches of the deep femoral artery (see Fig. 56-3). Most flaps in this region are based on branches of the lateral and medial circumflex femoral artery. Lateral muscle groups are supplied by the transverse, ascending, and descending branches of the lateral circumflex femoral artery, whereas the adductors and the gracilis are supplied by the medial circumflex vessels.³⁵ Perforating branches of the lateral circumflex femoral artery and the deep femoral artery supply the skin territories of the anterolateral and lateral thigh. The superficial femoral artery provides a segmental blood supply to the sartorius muscle and perforator vessels that supply the anteromedial thigh skin. The obturator and inferior gluteal vessels provide vascular supply to the skin of the medial and posterior thigh.^{8,36} As the superficial femoral artery approaches the knee through the adductor hiatus, it becomes the popliteal artery, giving off the sural, genicular, and saphenous branches.

With abundant surrounding soft tissue, most thigh defects can be closed by local tissue advancement or skin grafting. Large defects and wounds with exposed femoral vessels or femoral fractures, with or without exposed hardware, may occasionally require regional or even free flap coverage.³⁶ Pedicled rectus abdominis muscle and vertical rectus abdominis myocutaneous flaps are useful for large anterior thigh defects and coverage of exposed femoral vessels.³⁷ Regional flaps available for closure of proximal thigh, hip, and groin wounds include vastus lateralis, rectus femoris, and tensor fascia lata muscle flaps.

The vastus lateralis is a broad, thick muscle located deep to the tensor fascia lata in the lateral thigh. It can be harvested as a muscle flap or as a myocutaneous flap through inclusion of anterolateral thigh skin supplied by perforators through the muscle. Its harvest has little effect on ambulation, because the remaining muscles of the quadriceps group continue to function for knee extension.³⁸ The flap is supplied by the descending branch of the lateral circumflex femoral vessels. It is particularly useful for coverage of trochanteric and hip defects,³⁹ but it is also effective as a distally based flap³³ (Fig. 56-6) or a microvascular flap.⁴⁰

Fig. 56-6 A, This patient was involved in a snowmobile accident and presented with a lateral knee wound. The lesion measured 15 by 16.5 cm. B, Knee flexion revealed an open knee joint and an exposed patellar tendon. C, A distally based vastus lateralis muscle flap was harvested. D, Careful assessment of venous drainage is important with distally based flaps. A “supercharge” of venous outflow through anastomosis of a vena comitans of the descending branch of the lateral circumflex femoral artery with the large saphenous vein prevented venous congestion. E, The inset muscle provided complete joint coverage. F, The muscle flap was covered with a skin graft.

Fig. 56-6, cont'd G-I, The healed wound.

The rectus femoris muscle, located centrally in the anterior thigh, receives its vascular supply primarily from the descending branch of the lateral circumflex femoral vessels. Branches of the superficial femoral vessels and the ascending branch of the lateral circumflex femoral vessels may provide additional minor contributions.⁴¹ This muscle is not as bulky as the vastus lateralis and can be elevated as a myocutaneous flap with a sizeable skin paddle. Despite concerns that its harvest may adversely affect knee extension, reports show that other muscles of the quadriceps group compensate well in its absence.⁴²

The tensor fascia lata muscle, located in the lateral thigh, is a thin, flat muscle with numerous regional and microvascular applications. Based on the ascending branch of the lateral circumflex femoral vessels, this muscle can be elevated as a muscle, myocutaneous, myotendinous, or osteomyocutaneous flap.⁴³ It can also be raised in combination with the rectus femoris for large defects, as in a “muttonchop” flap.⁴⁴ The cutaneous portion of this flap receives T12- and L1-level innervation from the lateral femoral cutaneous nerve and branches of T12. With preservation of these nerves, sensation can be transferred with the flap. This can be useful for covering posterior pelvic defects where a lack of sensation can lead to recurrent pressure ulceration. In the thigh, this flap is used most frequently for coverage of trochanteric and ischial pressure sores but can also be applied to groin defects.^{45,46}

The sartorius muscle is supplied by segmental perforators of the superficial femoral vessels. Vascular communications between segmental territories allow the muscle to be elevated as a pedicled flap.⁴⁷ It is a long, thin muscle used most often in the thigh as a turnover flap for covering complicated wounds after vascular bypass.³⁷ It can also be advanced superiorly over groin defects or inferiorly over lateral knee defects.⁴⁸

The biceps femoris muscle is the lateral component of the hamstring muscle group of the posterior thigh. It is supplied by branches of the deep femoral vessels. It is used primarily for closure of ischial pressure ulcers sores,⁴⁹ but it can also be employed for defects of the anterior thigh and functional reconstruction of the quadriceps.⁵⁰

The gracilis muscle is a member of the adductor group of muscles, located along the medial aspect of the thigh between the adductor longus and semimembranosus muscles. It is supplied by a reliable branch of the medial circumflex femoral vessels that runs between the adductor longus and magnus muscles and by minor branches of the superficial femoral artery. It is effective as a pedicled or free muscle flap. Because of its reliability, it is used frequently for distal lower extremity defects in pediatric patients.⁵¹ The overlying skin can be included in transverse or longitudinal orientation relative to the muscle.⁵² The muscle is supplied by a well-characterized branch of the obturator nerve that accompanies the vascular pedicle as it approaches the muscle. The muscle is useful as an innervated flap for functional reconstruction of facial nerve paralysis and for upper and lower extremity defects.⁵³

Distal Thigh and Knee

Soft tissue availability significantly decreases distally in the thigh, resulting in greater challenges in designing local coverage options for supracondylar and knee defects. Thigh-based coverage options include regional muscle flaps, such as the sartorius and vastus medialis muscles, and fasciocutaneous flaps, including distally based anterolateral and anteromedial thigh flaps. Generally, the best regional tissue options are the gastrocnemius and soleus muscles. Fasciocutaneous flaps from the leg based on the saphenous artery and superficial branches of the superficial femoral artery have also been described.³⁵ For larger defects and in patients in whom these regional flap options are unavailable, microvascular tissue transfer is usually required (Fig. 56-7).

Fig. 56-7 Flap options for reconstruction of the distal thigh and knee.

Leg

The leg comprises four fascial compartments that contain the musculature and neurovascular structures (Fig. 56-8). The anterior compartment contains the tibialis anterior, extensor digitorum longus, extensor hallucis longus, and peroneus tertius muscles. It also contains the anterior tibial vessels and the deep peroneal nerve, which supply these muscles. The lateral compartment contains the peroneus longus and brevis muscles, which are innervated by the superficial peroneal nerve. The posterior compartment is subdivided into superficial and deep parts. The superficial portion contains the gastrocnemius, soleus, and plantaris longus muscles. The deep portion contains the flexor digitorum longus, the flexor hallucis longus, the popliteus and tibialis posterior muscles, the peroneal and posterior tibial vessels, and the tibial nerve. All muscles of the posterior compartment are innervated by the tibial nerve.

The popliteal artery gives off a number of branches, including the sural arteries that supply the gastrocnemius muscle and the genicular arteries (see Fig. 56-3). The popliteal artery further divides into the anterior tibial artery and a common trunk, which subsequently divides into the peroneal and posterior tibial arteries. The anterior tibial artery courses through the interosseous membrane to supply the muscles of the anterior compartment and the anterolateral skin of the leg. At the foot it becomes the dorsalis pedis artery, which contributes to the deep plantar arch. The posterior tibial artery supplies the skin of the posteromedial aspect of the leg and the muscles of the posterior compartment. In the foot, it divides to become the medial and lateral

Fig. 56-8 Cross-sectional anatomy of the leg.

plantar arteries. The peroneal artery supplies the muscles of the lateral compartment, the fibula, and the posterolateral skin of the proximal and middle parts of the leg.⁵⁴

Defects of the proximal and middle parts of the leg are usually managed with fasciocutaneous flaps or muscle flaps from the gastrocnemius or soleus muscles. Fasciocutaneous flaps based on the peroneal, anterior and posterior tibial, and sural arteries have been described.^{55,56} In general, muscle flaps in the leg are covered with skin grafts rather than elevated as myocutaneous flaps to reduce donor-site morbidity and to aid in incorporating the flap into the defect.

Supplied by the medial and lateral sural arteries, the gastrocnemius muscle is the workhorse flap for defects of the supracondylar area, the knee, and upper third of the leg. It is located superficially in the posterior calf and is divided into medial and lateral heads, both of which can be used as independent muscle flaps. The medial head is generally preferred for flap purposes, because it is longer and its use prevents dissection around the peroneal nerve, which overlies the origin of the lateral head in the subcutaneous tissue. The origin of either muscle can be divided and the vascular pedicle dissected into the popliteal fossa to increase the arc of rotation or advancement.⁵⁷ For larger defects both heads can be used, or one head can be used in combination with a soleus muscle flap. At least one of the three motor units must be preserved to maintain plantar flexion at the ankle. If the defect is small, a portion of the medial head may be returned to the donor site and reattached to the lateral head and the Achilles tendon for improved function.⁵⁸ The gastrocnemius may be elevated as a myocutaneous flap with a skin-fascial extension⁵⁹ or raised as an island flap that may reach the middle to distal femur.⁶⁰

The soleus muscle lies deep to the gastrocnemius muscle in the superficial posterior compartment. It originates from both the fibula and tibia and inserts into the deep surface of the Achilles tendon. The muscle can be split (hemisoleus flap) or transposed whole for coverage of the middle third of the leg.²

Although free tissue transfer has become routine for covering distal lower leg and foot defects in adults and children, local coverage options have been described and are used in many cases. Fasciocutaneous coverage includes distally based variants of the peroneal, anterior and posterior tibial, and sural artery flaps.⁶¹ These flaps can leave significant donor defects and may require a microvascular anastomosis to ensure adequate venous drainage. Axial fascial and adipofascial flaps limit donor defects but provide only thin coverage.⁶² Turnover adipofascial flaps are useful for coverage of proximal and distal defects. These flaps are not limited by the location of perforators and can be oriented horizontally or vertically, with a mobilized length/width ratio of up to 3:1⁶³ (Fig. 56-9).

The extrinsic extensors and flexors of the toes and ankle have been described for muscle coverage of the distal tibia and ankle region, but these are all small muscles with limited local usefulness.⁶⁴ The reversed hemisoleus muscle flap, based on a perforator from the posterior tibial artery, has also been described for distal leg coverage, but its utility is limited by problems with reliability.⁶⁵

Foot

The dorsum of the foot is covered by thin fascia that is continuous with the transverse and cruciate crural ligaments proximally and the plantar fascia medially and laterally (Fig. 56-10). Distally this fascia forms the sheath of the extrinsic extensor tendons. Deep to the long extensor tendons, the extensor digitorum brevis arises from the superior and lateral aspects of the calcaneus. This thin, broad muscle is supplied by the lateral tarsal branch of the dorsalis pedis artery and innervated by the deep peroneal nerve.

Fig. 56-9 Design of an adipofascial turnover flap. A handheld Doppler probe is used to identify perforating vessels, and the flap base is centered over this area. The total flap length is three times the length of the defect to be covered. The distal third covers the defect, the middle third is folded on itself, and the proximal third is the flap base. The fascia and fat of the flap are dissected from the overlying skin and underlying muscle. The skin is closed primarily, and the flap is covered with a skin graft. (Courtesy of Michael L. Bentz, MD.)

Fig. 56-10 Anatomy of the dorsum of the foot.

Fig. 56-11 Anatomy of the plantar surface of the foot.

The plantar surface of the foot has unique properties related to its function (Fig. 56-11). It is covered by glabrous skin, which is extraordinarily thick over the calcaneus and anchored to the underlying plantar fascia by thick septi, interspersed by loculations of semisolid fat. The plantar fascia extends from the calcaneus distally, and inserts into the skin and the sheaths of the flexor tendons. Superficial muscles of the plantar surface include the abductor hallucis and the flexor digitorum brevis, innervated by the medial plantar nerve. The abductor digiti minimi is located superficially on the lateral aspect of the foot and is innervated by the lateral plantar nerve. Muscles deep to the plantar vessels and nerves include the quadratus plantae, lumbricals, abductor digiti quinti, adductor hallucis, flexor hallucis brevis, and flexor digiti minimi brevis.

The vascular supply of the foot is derived from the continuation of the vessels of the leg (see Fig. 56-3). The anterior tibial artery becomes the dorsalis pedis artery, which gives off the medial and lateral tarsal arteries and the first dorsal metatarsal artery and continues as the deep plantar artery. The posterior tibial artery gives off the medial calcaneal artery before dividing into the medial and lateral plantar arteries, deep to the origin of the adductor hallucis. The lateral plantar artery unites with the terminal dorsalis pedis artery to complete the deep plantar arch. The peroneal artery terminates in the foot as the lateral calcaneal artery.

Large defects of the distal ankle and foot usually require free tissue transfer for coverage. A number of local flap options exist for treating small- to medium-sized defects in many areas. Distally based fascial or fasciocutaneous flaps from the leg or fasciocutaneous flaps supplied by the dorsalis pedis, medial and lateral plantar, and lateral calcaneal arteries may be used to cover certain defects.^{66,67} Muscle flaps useful for coverage of selected distal defects include the extensor digitorum brevis, abductor hallucis, abductor digiti minimi, flexor digitorum brevis, and flexor digiti minimi muscles⁶⁶ (Figs. 56-12 and 56-13).

The dorsalis pedis flap is a thin fasciocutaneous flap that can be raised as a proximally or distally based local flap or as a microvascular flap.^{68,69} Its pedicle is the dorsalis pedis artery and the venae comitantes when based proximally⁶⁷ and the first dorsal metatarsal artery and the venae comitantes when based distally.⁷⁰ Saphenous vein branches can provide venous drainage when

Fig. 56-13 Flap options for dorsal and plantar foot reconstruction.

the flap is used during microsurgery. Flap modifications have been described, including the inclusion of the vascularized tendon and extensor digitorum brevis muscle,⁷¹ elevation of the flap as a myofascial or adipofascial flap,⁷² inclusion of the second toe or metatarsophalangeal joint,⁷³ and neurotization of the flap through the deep or superficial peroneal nerves.^{68,69} The flap can be employed to provide sensate coverage of the plantar surface of the foot as either a pedicled or microvascularly transplanted flap⁷⁴ (Fig. 56-14). Problems of donor-site morbidity have been

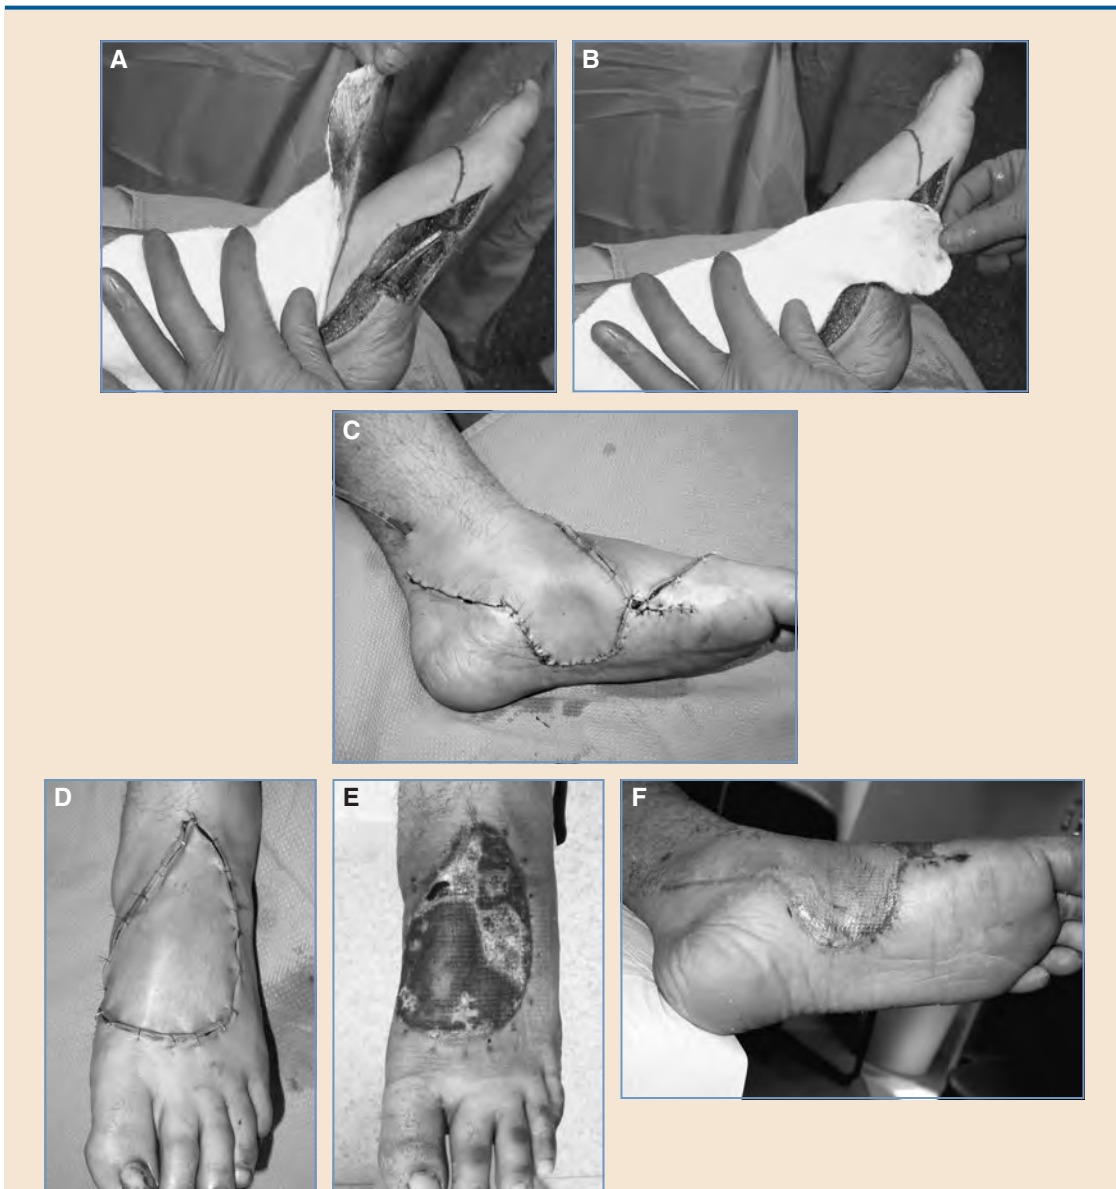

Fig. 56-14 This patient underwent plantar foot reconstruction with a sensate pedicled dorsalis pedis flap. **A**, Excision of a fibrosarcoma created a medial plantar foot defect. **B**, Simulation of transposition ensured a flap design of adequate length. **C**, The flap was elevated and inset. **D**, The dorsal foot donor site was covered with a full-thickness skin graft. **E**, Delayed healing at the donor site. **F**, The inset flap. (Courtesy of Ronald M. Zuker, MD.)

reported, including delayed healing and wound breakdown, pain, scarring, contracture, and infection.⁷⁵ The incidence and severity of these problems can be reduced with meticulous dissection of the donor site, preservation of the paratenon on tendons,⁷⁶ and the use of the extensor digitorum brevis muscle for tendon coverage.⁷⁷

The extensor digitorum brevis can be harvested with antegrade or retrograde flow through the dorsalis pedis artery to the lateral tarsal branch that supplies the muscle. Proximally based flaps are well described for covering wounds of the proximal part of the foot and the ankle.⁷⁸ The extensor digitorum brevis can also be included in the fasciocutaneous territory of the dorsalis pedis artery for a myocutaneous flap.⁷⁹ The distally based flap is useful for coverage of the middle to distal foot.⁸⁰ The extensor digitorum brevis is harvested through a dorsal incision lateral to the dorsalis pedis vessels. The lateral tarsal arterial branch is identified between the extensor digitorum longus and extensor hallucis longus tendons and is traced into the muscle. The dorsalis pedis artery may be ligated distally or proximally as needed to improve the arc of rotation. Before ligation of the artery, the integrity of the posterior tibial circulation must be confirmed to prevent vascular compromise of the foot. The superficial surface of the muscle is dissected, preserving the long extensor tendons and the superficial peroneal nerve. The short extensor tendons are divided, and the deep surface is dissected off of the tarsal bones. The sinus tarsi branch from the lateral tarsal artery must be identified and divided to prevent injury to the pedicle.

The lateral calcaneal artery flap is based on the terminal branches of the peroneal artery located between the Achilles tendon and peroneal tendons (Fig. 56-15). The flap is innervated by the sural nerve. This flap has been described with various modifications for Achilles tendon coverage and reconstruction of calcaneal and plantar heel defects, including as a transposition flap, island flap, and V-Y advancement flap.⁸¹ This flap is useful for transferring durable, sensate tissue without sacrificing the plantar arteries or nerves.

Heel defects are difficult to reconstruct because of the specialized tissue requirements of sensation and durability. Skin grafts, although frequently suboptimal, can be used in any portion of the plantar foot as long as adequate subcutaneous tissue is present.⁸² Sensate flaps are ideal for heel coverage and can be provided by the calcaneal artery flap, including the medial calcaneal nerve, or the medial plantar artery fasciocutaneous flap, which includes the medial plantar nerve. Hidalgo and Shaw^{83,84} described the rotation of a medially based flap of heel tissue that preserves both the medial and lateral plantar nerves. Intrinsic muscle flaps, including the flexor

Fig. 56-15 Design of a lateral calcaneal artery flap. The position of the artery is confirmed with a handheld Doppler probe. The flap is elevated with inclusion of the artery and can be used for coverage of the lateral malleolus or Achilles tendon. The donor site is covered with a skin graft. (Courtesy of Michael L. Bentz, MD.)

digitorum brevis and the abductor hallucis brevis, are useful for small- to moderate-sized and deeper defects.⁸⁵ Their coverage is limited because of their relatively small size and limited potential for advancement. Large defects and those with exposed hardware or bone often require free tissue transfer.⁸⁶ Muscle flaps are usually indicated for larger defects and when osteomyelitis is present. Innervated fasciocutaneous flaps are best for acute defects when sensation could be valuable.^{86,87} Muscle flaps are generally preferred over fasciocutaneous flaps for plantar coverage, because they provide greater stability and create less shear between the flap surface and the deep tissues with walking; however, this is debatable. Both types of flap show good function over time, and selection should be based on the patient's characteristics and needs.⁸⁷ Noninnervated flaps show some degree of sensory recovery, although it does not reach the level of two-point discrimination or light touch.⁸⁸

Dorsal foot defects can be covered with skin grafts if the paratenon is preserved or if exposed tendons are excised (Fig. 56-16). Larger wounds, particularly with exposed bone, usually require free flap coverage. Ideally the tissues used are thin, pliable, and durable.⁸⁹ Coverage of distal defects with local flaps such as reverse-flow dorsalis pedis and extensor digitorum brevis flaps, based on the lateral tarsal or first dorsal metatarsal arteries, has also been described.^{70,79}

Fig. 56-16 This patient had a distal dorsal foot wound resulting from a lawn mower accident. This case demonstrates complex wound coverage using a sequential approach to wound management. **A**, Initial presentation with exposed bone and tendon. **B**, Appearance after local flap coverage of tendon and bone. **C**, Appearance after NPWT therapy for 3 days. **D**, Appearance after split-thickness skin grafting. **E**, The healed wound.

Distal plantar defects are best covered with local sensate flaps, such as fillet flaps from central digits or small V-Y perforator flaps.⁹⁰ Distally based muscle and fasciocutaneous flaps have been described, including the abductor digiti minimi, flexor hallucis brevis, and medial plantar flaps. Non-weight-bearing portions of the plantar foot can be favorably managed with skin grafts.

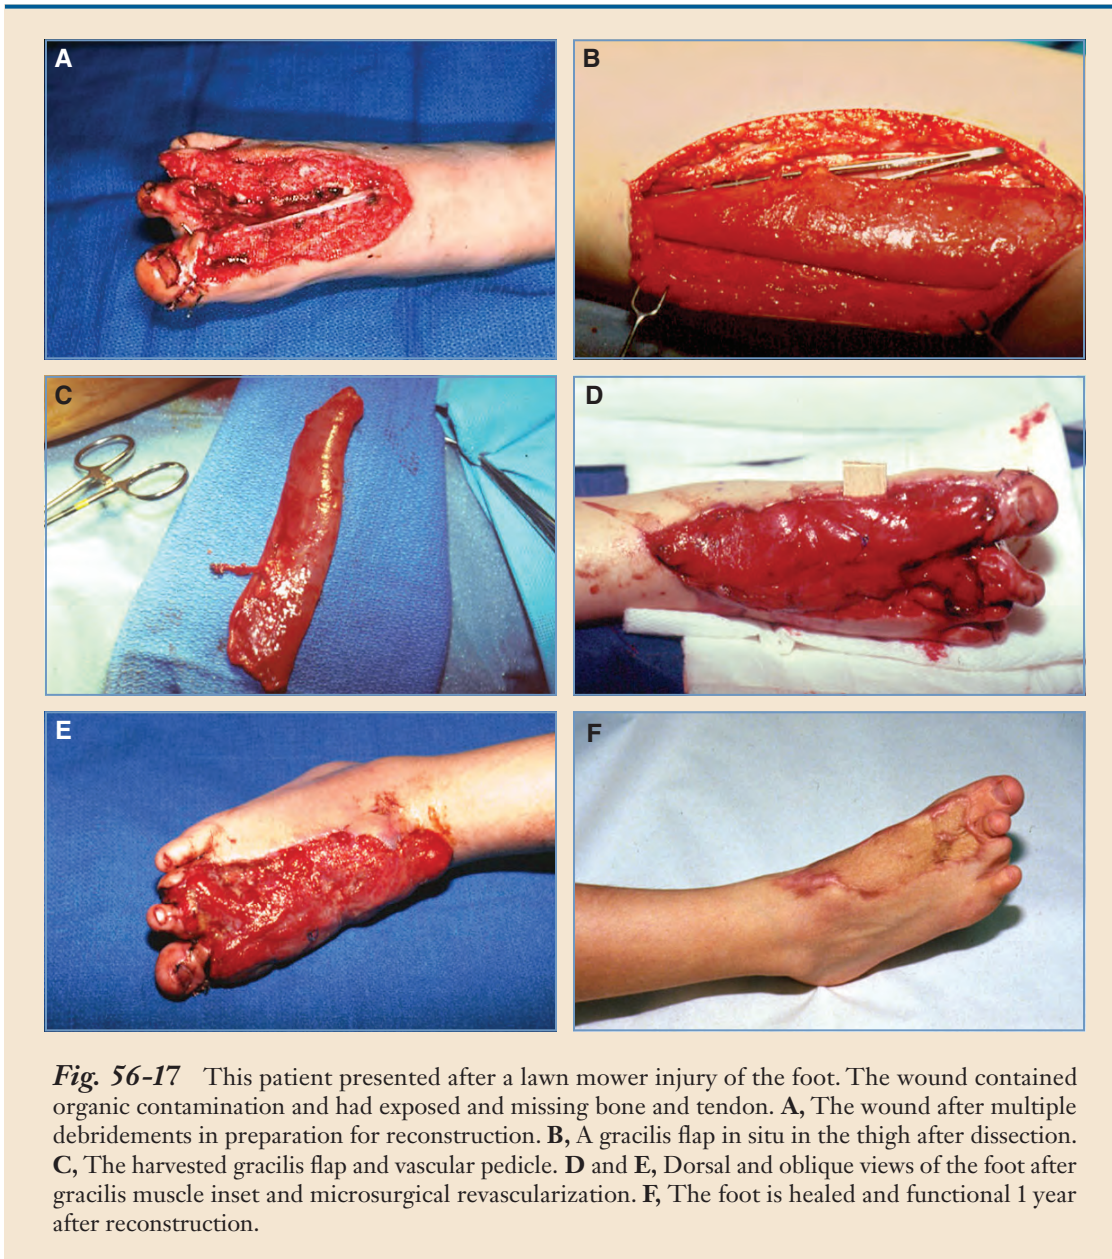

MICROSURGICAL TRANSPLANTATION

Microvascular free flaps have become the benchmark for covering difficult defects of the lower extremity.^{6,91,92} Indications for microvascular reconstruction include high-energy injuries, many middle and most distal tibial defects, radiation-related wounds, tumor reconstruction, and osteomyelitis; it is also useful for part of the treatment for skeletal nonunion. Over the past 30 years, microsurgery has achieved a level of sophistication that has refocused the reconstructive goals from tissue survival and coverage to improvement in appearance, limitation of donor-site morbidity, and preservation of function.

Harii and Ohmori⁹³ originally reported on pediatric free tissue transfer in 1975. They harvested free groin flaps for coverage of ankle defects in two 4-year-old children. Since then, numerous applications of microvascular flaps in children have been described, ranging from toe-to-thumb transfer to esophageal reconstruction with jejunal segments.⁹⁴ Congenital problems, such as congenital hand deformities,⁵¹ account for a significant portion of free tissue transfers performed in children, but lower extremity trauma requiring free flap closure in pediatric patients has been reported.^{91,95,96} In 2008 Upton and Guo⁹¹ reported on a series of 433 free tissue transfers (108 to the lower extremity) in pediatric patients, with a 99.8% success rate and 9% complication rate. Indications for free tissue reconstruction of lower extremity defects in children are similar to those in adults and include avulsion injuries of the distal tibia and foot, injuries involving defects of both soft tissue and bone, extensive soft tissue deficiency, osteomyelitis, failure of other reconstructive techniques, and unstable scars or skin grafts.^{20,21}

Free tissue transfer in pediatric patients offers the advantage of minimal comorbidities, robust wound healing, good sensory/motor regeneration, and the benefit of adaptation and growth of transferred tissue. Pediatric microvascular surgery may require technical modifications based on small vessel size and structural differences of the vessels.^{92,96,97} The walls of the vessels are thinner and more fragile than those of adults, leading some surgeons to recommend the use of systemic anticoagulation in all pediatric free flaps.^{95,97} Larger series, however, have not shown this to be necessary.⁹¹ The absence of atherosclerotic changes in the vasculature of pediatric patients is advantageous to surgeons.⁹⁸ For most cases that do not involve substantial trauma or congenital anomalies, routine preoperative angiography is unnecessary if pulses are palpable.⁹⁹ Duplex ultrasound imaging, MRA, and CTA are less invasive than traditional angiography and may provide anatomic detail information that can help with flap planning and decision-making regarding the recipient site.¹⁰⁰ Other considerations related to microsurgery for pediatric patients include a two-team approach to shorten operative time and careful attention to blood loss. Many surgeons do not give aspirin for postoperative anticoagulation because of concerns about an association between Reye syndrome and aspirin use.¹⁰¹ However, this association has been questioned in recent years.¹⁰²

Many of the massive defects that occur after significant lower extremity trauma require the bulk and/or surface area of rectus and latissimus muscle flaps, which are then covered with split-thickness skin grafts.¹⁰³ The gracilis is an ideal flap for smaller defects in children because of its well-hidden donor scar and minimal morbidity (Fig. 56-17). Muscle flaps are also indicated in cases of osteomyelitis and bony nonunion, because they provide increased blood flow and more complete dead space obliteration.¹⁰⁴ However, in following Gilles's concept of "replace like with like," tissue transferred to reconstruct a wound should be tailored to match recipient site requirements.¹⁰⁵ The dorsum of the foot and the ankle areas are ideally covered with thin, pliable

tissue, such as that provided by skin-grafted fascial flaps or fasciocutaneous flaps from the forearm, thigh (anterolateral thigh), scapular/parascapular, or temporoparietal donor sites.⁹¹ A free-style approach to elevating perforator free flaps has demonstrated early success using an anterolateral thigh perforator, a superficial circumflex iliac artery perforator, an upper medial thigh perforator, and a posterior interosseous perforator.¹⁰⁶ The unique tissue found in the weight-bearing areas of the plantar foot is not entirely replicated by any single tissue type, its ideal replacement is controversial. Muscle flaps such as the rectus abdominis or latissimus dorsi provide bulk to re-create the heel pad, but limited sensation or lack of sensation may lead to breakdown of skin grafts over these flaps.¹⁰⁷ Fasciocutaneous and myocutaneous flaps provide better skin quality and

the possibility of cutaneous sensation, but they are subject to shear and are often bulky, creating problems with footwear.¹⁰⁸

Although reported free flap success rates in the pediatric population are comparable or better to those in adults, postoperative complication rates ranging from 9% to 35% and long-term problems with the reconstructed limb have been reported.^{91,109} Limb discrepancy, valgus and varus deformities, and degenerative arthritis of the ankle are common consequences of the original injury, with bulky flaps, ulceration of skin grafts, contractures, and hypertrophic scars related to flap reconstruction contributing to significant additional functional problems. Wei et al¹⁰⁹ recommended special precautions with the preoperative assessment, planning, and execution of surgery and with the postoperative care of pediatric patients undergoing microvascular lower extremity reconstruction. For example, in patients requiring preservation of shoulder function, they suggested partial latissimus muscle harvest and advocated adequate dorsal foot coverage to prevent contractures and subsequent toe deformities, which can occur as the foot grows.⁹⁵

In general, long-term donor-site morbidity has not yet been well defined in pediatric patients. Donor-site considerations include preventing tight donor-site closures and using fasciocutaneous flaps to facilitate maintenance of donor-site growth characteristics. Particular care is required with the rectus abdominis muscle and radial forearm flap because of their importance for abdominal wall stability and upper limb vascular inflow, respectively. The latissimus dorsi flap should not be used in patients with contralateral shoulder muscle paralysis and in patients who rely ideally on crutches when possible or a wheelchair for locomotion.^{91,92} The psychological consequences of donor-site scars should not be minimized, because visible scars can be the source of significant ongoing distress to children and parents.

Postoperative management of free tissue transfers can be challenging, especially in younger children. Fear and pain are more common in children and can cause flap-compromising vasoconstriction in the early postoperative period. Rinker et al¹³ recommended early visits from social workers and child psychologists to assist with the expected difficulties in adjusting to the injury and hospitalization. They also found that epidural catheters can be very effective in controlling postoperative pain and reducing narcotic use. Sedating patients for procedures such as dressing changes, pin removal, IV changes, and difficult blood draws is essential.⁹²

Protecting the flap in pediatric patients can be problematic. Splinting or casting (with a flap window), trapeze suspension, and triangulated external fixators are useful techniques for maintaining elevation and fixation.¹¹⁰ Positioning must be adjusted carefully to prevent placing pressure on important vascular structures. This is particularly vital when the posterior tibial vessels are used as recipient vessels for distal leg and foot reconstruction. The leg often requires suspension to prevent venous compression and flap congestion.

SKELETAL RECONSTRUCTION

High-energy tibial injuries with combined skeletal and soft tissue injuries should be managed with a combination of orthopedic and plastic surgery approaches.¹⁰⁵ After the initial resuscitation and evaluation, surgeons should determine the extent of injury and the potential for salvage. Most injured extremities can be salvaged using currently available techniques. Patients with severe injuries might be better served with a definitive amputation than with preservation of a nonfunctional, painful limb after limb salvage.¹¹¹ If reconstruction is planned, skeletal stability is obtained. In the treatment of skeletal injuries in adults, immediate internal fixation is preferred for open fractures without bone loss or significant concomitant injury, whereas in children, external fixation is more commonly indicated.¹¹² Severely traumatized lower extremities in patients of all ages often require external fixation.¹⁰⁵ After the soft tissue is reconstructed, persistent skeletal defects can be addressed by bone grafting, bone transport, or free tissue transfer.

Defects up to 5 cm long can usually be reconstructed with conventional nonvascularized bone grafting,¹⁰⁵ but the supply of cancellous bone graft may be limited in smaller children. Complications, including fracture, nonunion, and infection, occur in 10% to 20% of patients undergoing grafting of large bony defects.¹¹³

Posttraumatic tibial defects larger than 5 cm are often managed with distraction osteogenesis, bone transport, or vascularized free tissue transfer. The skeletal defect is reduced with a temporary antibiotic spacer or limb shortening. After the soft tissue heals, the bone is lengthened to fill the bone defect or to restore limb length. Ilizarov¹¹⁴ developed this technique, which has been successfully used in pediatric patients for a variety of skeletal defects.¹¹⁵ Current methods of bone transport allow distraction osteogenesis of 1 to 1.5 mm per day. Reported complication rates range from 5% to 25%.¹¹⁶

Free tissue transfer for reconstructing bony defects of the lower extremity primarily involves the use of a contralateral free fibula transfer.^{109,117} Advantages of free tissue transfer include the ability to restore adequate length with augmentation of local blood supply to the traumatized area. Preserving the bone's vascularity facilitates survival of osteoblasts and osteocytes and healing at the native bone-graft interface without the need for replacement of the graft by creeping substitution.¹¹⁸ The use of vascularized bone may provide sufficient healing potential to reduce the number of procedures required to achieve union, compared with distraction osteogenesis.⁴ In patients with congenital pseudarthrosis of the tibia, this technique has markedly improved the ability to achieve union, compared with conventional bone grafting.¹¹⁹ In addition to these influences on bone healing, the technique enhances growth potential through the inclusion of physes in the flap. The proximal physis contributes 60% of fibular growth and can be transferred with the epiphysis and metaphysis of the fibula using the anterior tibial vessels or peroneal and lateral inferior genicular vessels in combination.¹²⁰ Epiphyseal decancellation can be performed to reshape the flap while preserving the articular surface, periosteum, and physis.¹²¹ Because additional soft tissue can be incorporated in free fibula flaps, they are ideal for managing composite defects.

The smaller caliber of the fibula creates a mismatch in size at the fibula-tibia interface. Controlled loading of the fibula results in remodeling and hypertrophy, but stress fractures occur in 25% to 40% of cases.¹²² The use of a folded free fibula (double- or triple-barrel) increases the cross-sectional area, improving the tolerance of mechanical stress and torque. This technique reduces the risk of fracture and decreases the time to ambulation from 15 months to 6 months.¹²³

Combining free fibula flaps and massive bone allograft has been described for reconstructing bony oncologic defects of the lower limb.¹²⁴ This technique incorporates the mechanical properties of allograft with the biologic properties of vascularized tissue, resulting in earlier stability and incorporation.¹²⁵

TISSUE EXPANSION

Tissue expansion is often used in pediatric patients to manage giant congenital nevi and secondary reconstruction of burn scars.¹²⁶ The technique allows the resurfacing of defects with local tissue of the same color, texture, and thickness. Tissue expansion has a reported complication rate of 9.6%, with expander infection rates ranging from 4.4% to 9.3%, necessitating a low threshold for initiation of antibiotics.¹²⁷ With a reconstructive success rate of 98.3%,¹²⁷ however, tissue expansion has revolutionized the management of large cutaneous defects, anomalies, and scars.

Despite the high success rates associated with tissue expansion, the lower extremity has been found to be an unfavorable location for this technique. Complication rates with expansion in the extremities, especially the lower extremities, are significantly higher than in the scalp, face, and trunk. Problems encountered include expander extrusion, rupture, infection, flap necrosis (both during and after expansion), neurapraxia, and bone resorption.^{127,128} Several theories have been proposed for regional differences in complication rates, including limited tissue availability, geometry of flap design, and problems with vascular supply.¹²⁷

Unacceptably high complication rates are associated with tissue expansion below the knee and in limbs with open wounds.¹²⁸ Current indications for tissue expansion in the lower extremity include correction of contour irregularities, excision of unstable scars or skin grafts, excision of congenital nevi, and secondary correction of burn scars. When tissue expansion is performed in the leg, the following recommendations may minimize the risk of complications^{128,129}:

- In the thigh, incisions for placing an expander should be made at the edge of the defect, whereas at the knee, a remote incision may be less prone to dehiscence.
- A large, single expander should be placed in the subcutaneous plane.
- Expansion should be controlled by patient discomfort and skin blanching. Expansion in this area can take a significant amount of time (from 8 to almost 30 weeks in one series¹²⁹).
- Planned flap advancement should be simple and without a rotational component.
- Complications must be recognized early and treated aggressively.

Additional uses of tissue expansion in the lower extremity include preexpansion of free flaps and expanded, full-thickness skin grafts for lower extremity reconstruction¹²⁷ and preexpansion of dorsal foot skin before clubfoot surgery.⁵

LIMB REPLANTATION

Replantation in the lower extremity can be attempted for pediatric patients with a limb amputation from a sharp or guillotine-type injury with minimal additional soft tissue trauma. Factors most likely to affect outcome include the mechanism of injury, the duration of warm ischemia, and the extent of soft tissue injury.¹³⁰ Unfavorable outcomes are associated with long ischemia time (8 to 10 hours), more proximal injuries, multilevel trauma, and avulsion or crush injuries.^{15,131,132}

Long-term follow-up with children who have undergone limb replantation shows growth of the replanted limbs, although disparity in length between the replanted and unaffected limbs is common.^{131,133,134} Distraction osteogenesis has been successfully used to equalize limb length and to improve rehabilitation.¹³⁴ Insufficient neural regeneration is one of the primary factors affecting the ultimate functional outcome of lower extremity reconstructive efforts. Pediatric patients have an improved ability to heal nerve injuries and have been shown to achieve excellent sensory recovery after leg replantation.^{132,135} Although problems such as limb-length discrepancy, joint contractures, and muscle weakness may prevent completely normal function, the long-term functional outcomes of replanted lower extremities in children are generally very good¹³²⁻¹³⁴ (Fig. 56-18). The reconstructive surgeon should be an integral part of the decision-making process in severe lower extremity trauma. Microsurgical salvage of devascularized tissue can provide a worthwhile outcome.

Fig. 56-18 Incomplete amputation of midfoot connected by small skin island with devascularization of distal part, as scheduled by the trauma team for amputation revision. Consultation with the reconstructive team led to a fairly simple salvage procedure. **A**, Preoperative appearance of incomplete amputation. **B**, Intraoperative appearance after shortening, stabilization, revascularization, and reinnervation. **C**, Lateral view of the late result. **D**, Dorsal view of the late result. **E**, Plantar view of the late result. **F**, Minimal deformity of the revascularized right foot. KEY POINTS

- Lower extremity defects in children are most frequently a result of trauma; however, congenital anomalies and oncologic defects can occur.
- Pediatric patients with lower extremity defects, and their parents, often have a high degree of anxiety about the injury, compounded frequently by the inability to understand and comply with treatment recommendations.
- The potential effects of injury, reconstructive surgery, and donor-site harvest on future growth must be considered when planning treatment.
- Most local, regional, and microvascular techniques used in adults can be successfully applied to pediatric patients.
- Tissue expansion and distraction osteogenesis can be valuable adjunctive methods for reconstructing pediatric lower extremity trauma wounds.

Evolving Concepts in Pediatric Imaging

Steven T. Lanier • Arun K. Gosain

he evolution of modern technology has provided clinicians with numerous sophisticated imaging modalities to aid in diagnosis and treatment planning for surgical conditions. In a relatively short time we have seen an expansion of the imaging armamentarium from simple radiographs to include real-time fluoroscopy and angiography, CT, MRI, MRA, MRV, and more recently, cone-beam CT (CBCT). Advanced imaging modalities have also facilitated virtual planning of complex surgical procedures.

The treatment of pediatric patients with congenital or acquired malformations best exemplifies surgery involving numerous sophisticated imaging modalities. Clinicians should understand the indications, accuracy, advantages, and disadvantages of various imaging modalities. Because concerns over radiation exposure are heightened for children, surgeons should adequately understand these risks and be able to quantify them for concerned parents and decision-makers.

We begin with a brief overview of the imaging modalities commonly employed in pediatric plastic surgery, followed by a discussion of the evidence-based risks of radiation exposure. The rest of the chapter is organized by common conditions treated by pediatric plastic surgeons: craniosynostosis, cleft lip and palate, vascular malformations, and craniofacial trauma. For each condition, we describe how appropriate imaging modalities are employed to guide the workup and surgical treatment. We conclude with a discussion that anticipates future trends in imaging, specifically the growth of virtual surgical planning (VSP) as a heuristic for complex craniofacial procedures.

REVIEW OF TECHNOLOGIES

Radiography

An X-ray is a high-frequency, short-wavelength, high-energy form of electromagnetic radiation that can pass through structures in the body. When directed toward a detector, film or digital, X-rays form a contrasted image based on their differential absorption by tissues such as bone, muscle, fat, and air. Tissues with a higher density and atomic number, such as calcium-rich bone, more readily absorb X-rays and appear white on a radiograph, whereas air-filled structures, such as lung, absorb a minimal amount of X-rays and appear relatively black on a radiograph.¹

Computed Tomography

The English engineer Gregory Hounsfield,² of the eponymous Hounsfield unit, first described his invention of CT scanning in 1972. A CT scanner employs a narrow, fan-shaped beam of radiographs toward a digital detector in a rotational arc around the patient to create a series of cross-sectional images, or axial “slices,” as the patient moves longitudinally through the gantry. Computer algorithms take these cross-sectional slices and generate views in other two-dimensional planes, sagittal and coronal, and in three-dimensional (3D) reconstructions.³ Most modern medical CT scanners use multidetector CT, which uses a large detector arc that acquires up to 64 axial slices simultaneously.⁴ Resolution between axial slices ranges from several mm to as low as 200 μm , depending on machine settings.

CT is optimal for imaging and diagnosing bony abnormalities such as those found in many craniofacial differences. CT images of soft tissues are more difficult, because these tissues absorb X-rays poorly, although visualization can be augmented by the addition of iodine-based contrast agents.

Cone-Beam Computed Tomography

CBCT was first developed in Japan in the early 1990s and became commercially available in the early part of the twentieth century.⁴ Its name derives from the use of a larger, cone-shaped X-ray beam as opposed to the fan-shaped beam employed by traditional CT scanners. CBCT employs smaller and less-expensive components that require less electrical energy than its fan-shaped counterpart.⁵ As a result, CBCT technology allows faster image acquisition at a lower radiation dose and lower cost, compared with traditional CT. Resolution with CBCT is as high as only 70 μm between axial slices; however, in clinical use, accuracy of up to 0.5 mm is possible.⁴ Data collected by a CBCT scanner can be exported to other imaging formats such as panoramic or cephalometric radiographs. Furthermore, CBCT prevents the shortcomings of these traditional imaging modalities, which include insufficient information and a superimposition of anatomic structures.⁵ Limitations of CBCT include poorer soft tissue visualization than with traditional CT.⁴

Micro Computed Tomography

Micro CT scanning technology is capable of producing images of as high as 5 to 50 μm resolution, making it a highly useful tool for research purposes.⁴ However, because it is not employed clinically, it will not be discussed further in this chapter.

Fluoroscopy and Angiography

In contrast to the static images obtained on plain radiographs, fluoroscopy involves continuous X-ray emission through the body to a detector for real-time visualization of the movement of

structures or of the passage of contrast agents through a structure. Angiography involves the use of fluoroscopy after the intravenous injection of a contrast agent to image vascular structures or malformations.⁶

Magnetic Resonance Imaging

MRI involves placing a patient in a magnetic field that aligns the axis of spin of hydrogen nuclei in the body. Hydrogen is used because of its high concentration in water and fat, two of the most abundant tissues in the human body. Radio wave frequency is then pulsed to the field, which causes the hydrogen nuclei to sequentially resonate and relax, emitting a radio wave that is detected by an MRI detector. Various tissues relax at differential rates, resulting in contrast between structures. T1 relaxation refers to the time it takes for the hydrogen nucleus' magnetic vector to return to its original state, whereas T2 relaxation refers to the time it takes for its spin to return to its premagnetization state.⁷

The long-wavelength, low-frequency, low-energy radio waves employed in MRI do not present the same concerns about radiation exposure as do the X-rays employed in CT. MRI is often the optimal imaging modality for examining soft tissue.⁴

Ultrasound Imaging

Ultrasound imaging uses a probe to emit high-frequency sound waves across structures in the body. When these sound waves encounter the interface between two different types of tissue, such as bone and soft tissue, some of the sound waves are reflected back toward and detected by the probe. Using the time to detection of the returning waves, together with the speed of sound, the information from the probe is turned into a two-dimensional image displaying the relative location of structures encountered.⁸

RADIATION EXPOSURE

X-rays are high-energy, ionizing radiation that can excite electrons from their orbits, creating free radicals that cause damage to adjacent DNA molecules.⁹ Concerns about the development of heritable mutations and cancer as a result of radiation exposure are heightened in pediatric patients for several reasons.¹⁰ Epidemiologic studies have shown that children are more sensitive to radiation than adults, probably because children have a higher percentage of rapidly proliferating cells. Furthermore, children have a longer life expectancy than adults, thus they have more time to express the effects of radiation damage.

The effects of radiation vary by tissue type. The cumulative amount of radiation exposure to a patient for a given study is often estimated using the concept of an effective dose unit, which accounts for the measured radiation exposure to each tissue type during a study and weights this exposure based on the radiosensitivity of each tissue type.¹¹ Structures in the head receive a relatively low weight compared with more radiosensitive tissues such as gonadal tissue, breast, and colon.¹¹ However, an effective dose unit is a measure of whole body risk; thus, for the purpose of assessing the risk of a focused examination such as a craniofacial CT scan, reporting of radiation exposure in milliGray (mGy), or the equivalent milliSievert (mSv), is more common.

Jaffurs and Denny¹² analyzed the total radiation exposure of 77 pediatric patients at a single center who underwent thin-slice head or face CT with 3D reconstructions as part of the diagnosis, treatment planning, and postoperative evaluation for either cranial vault remodeling or midface distraction. Nonsyndromic craniosynostosis patients underwent an average of four CT scans, and syndromic craniosynostosis patients underwent an average of 9.73 CT scans over the total course of treatment, with an average radiation dose of 1.39 mSv per CT scan. The total ex-

posure in nonsyndromic and syndromic craniosynostosis patients was roughly 5.6 and 13.5 mSv, respectively. Whether the reported dosages reflect a calculation of brain-specific radiation exposure is not evident in this study. As a frame of reference, each of us receives an effective dose from natural background radiation of about 3.0 mSv each year, half of which is from radon in the soil, although it can be as high as 14.8 mSv for those living at high altitudes.^{12,13}

High-quality evidence on the cancer risk of CT radiation in children has become available in recent years from three international long-term cohort studies. Traditional estimates of radiation risk to children from CT have been extrapolated from the lifespan study of atomic bomb survivors from Nagasaki and Hiroshima, although such extrapolations are fraught with uncertainty and questionable methodology.¹² Inferring individual radiation risk from population-based epidemiologic data is problematic, because it does not account for important factors such as the age at exposure, an individual's genetic predisposition, and particular tissues exposed, which vary significantly in radiosensitivity.¹⁴ These newer studies shed some much-needed light on this important topic.

Most relevant to our patient population is a 2012 study published by Pearce et al¹⁵ in *Lancet*. In a large, retrospective cohort study, the authors found a relative risk of 2.82 for the development of a brain tumor in children who received a cumulative dose of 50 to 74 mGy from head CT, compared with nonirradiated controls. However, in absolute numbers, only 135 of 176,587 (0.076%) patients followed in the entire study developed a brain tumor. The authors estimated that the radiation exposure from head CT accounted for an additional one attributable case of brain tumor per 10,000 head CT scans performed in patients younger than 10 years of age.

Despite low absolute risks, all efforts should be made to minimize the radiation dose to pediatric patients. This is reflected in the As Low As Reasonably Achievable (ALARA) principle advocated by the Society for Pediatric Radiology. Children with craniofacial differences often require multiple interventions and monitoring throughout childhood, thus it is important to remain cognizant of the lifetime attributable risk to these patients. This begins with judicious use of imaging only when indicated. Furthermore, several adjustable parameters affect the total radiation dose for a given study, including tube voltage and current, scan time, and scan field of view.⁵ Surgeons, in collaboration with pediatric radiologists and technical support staff, should ensure proper settings are employed for craniofacial applications in pediatric patients to use the least radiation to provide sufficient image quality. Newer technologies that employ automated tube current modulation automatically adjust tube current using a feedback circuit based on the attenuation value of the previous image, which results in the minimum radiation dosage necessary for sufficient image quality.⁵ CBCT employs significantly lower radiation, and its use should help to meet this goal.

Protective adjuncts, such as leaded eyeglasses and thyroid shields, for particularly radiosensitive organs have been shown to reduce exposure during maxillofacial CBCT.^{16,17} When appropriate indications for ordering examinations are observed and protocols are followed, the benefits from having an accurate diagnosis to guide treatment planning nearly always outweigh risks to the child.

INDICATIONS

Craniosynostosis

CT with 3D reconstruction is a highly accurate imaging modality for evaluating cranial sutures and cranial shape and has replaced plain radiography as the standard for imaging cranial sutures.¹⁸ Nonetheless, whether a CT scan is necessary in all patients with a suspected sutural abnormality

is questionable. For patients with simple, single-suture, nonsyndromic craniosynostosis, experienced clinical assessment is highly accurate, and CT scanning is marginally useful in operative planning or identification of intracranial abnormalities that will change management.^{18,19} Although associated abnormalities such as ventriculomegaly and prominent extra-axial CSF are common, incidental findings that require intervention are rare.²⁰ Furthermore, the traditional study of a plain radiograph remains cost effective and a useful adjunct in patients with a low pretest probability of craniosynostosis based on clinical examination.²¹ Thus routine CT imaging is not required, and the benefits may not outweigh the combination of radiation risk, the possible need for sedation to obtain an adequate study, and resource utilization.

In contrast, 3D CT is a powerful tool for preoperative assessment and planning for syndromic craniosynostosis (Fig. 57-1). Traditional skull radiographs have a low sensitivity to detect complex

Fig. 57-1 A-C, 3D reconstructions of a low-dose craniofacial CT scan obtained to aid diagnosis and preoperative planning for a 6-year-old male with Apert syndrome. The patient presented with pansutural craniosynostosis, resulting in papilledema and thumb-printing of the calvaria, suggestive of elevated intracranial pressure. D-F, 3D reconstructions of a low-dose craniofacial CT scan obtained 1 year after anterior cranial vault remodeling, frontoorbital advancement, and frontal sinus obliteration. The patient also had midface hypoplasia and shallow orbits characteristic of Apert syndrome.

and minor sutural craniosynostosis.²¹ Low-dose spiral multidetector CT with 3D reconstruction allows not only an identification of major sutures involved in multisuture craniosynostosis, but also characterizes the involvement of minor skull-base sutures and facilitates an accurate characterization of supraorbital rim deformities and nasal root deviation.²² CT is also useful for evaluating brain structural abnormalities that have a higher degree of association with syndromic or multisuture craniosynostosis, such as hydrocephalus, ventricular dilation, brain hemiatrophy, chronic subdural hematoma, and agenesis of the corpus callosum.²¹

Routine postoperative screening CT is not recommended for patients undergoing cranial vault remodeling. A review of patients undergoing routine postoperative CT showed no change in management or prognosis based on the scan, with the exception of patients with concomitant shunt placement for hydrocephalus.²³ However, an understanding of changes in cranial vault volume over time until skeletal maturity is highly useful. For this purpose, a high degree of correlation has been shown between the use of 3D photography and 3D CT, and some authors have advocated this as an alternative to track cranial development over time without the risks of radiation exposure.²⁴

Multiple authors have investigated the utility of ultrasound imaging as an alternative to CT for diagnosing single- and multiple-suture craniosynostosis and have found it to be a highly sensitive and specific alternative to CT.²⁵⁻²⁷ Given its high negative predictive value, ultrasound scanning has been suggested as an initial screen in suspected infants, and CT is recommended for cases in which ultrasonography results are abnormal or equivocal or when needed for preoperative planning.²⁸ A potential drawback of ultrasound imaging is its operator dependence; thus experienced technicians help to increase accuracy.

The use of MRI with novel parameters to optimize visualization of the soft tissue–bone interface has also been reported, allowing 3D cranial reconstruction and accurate diagnosis of craniosynostosis.²⁹ However, the potential need for lengthy sedation or general anesthesia is a drawback for this modality and a reason it is not widely used.

CBCT offers substantial promise to produce high-quality 3D reconstructions for planning and postoperative evaluation of craniosynostosis patients, with a fraction of the radiation dose and cost of traditional CT scan. However, it is not widely used for this indication. This indication for CBCT is discussed further in the section on VSP.

Cleft Lip and Palate

In patients with cleft lip and palate, several indications exist for multiyear imaging and for using a comprehensive team approach. Assessment of velopharyngeal function after cleft palate repair is important as these children age, because evidence of velopharyngeal inadequacy may necessitate a secondary palatal procedure. Evaluation by a trained speech and language pathologist, multiview videofluoroscopy, and video nasopharyngeal endoscopy are important adjuncts for assessment.³⁰ Multiview videofluoroscopy allows real-time visualization of the velopharyngeal mechanism in multiple views. A contrast material is injected into a patient's nares and fluoroscopic images are recorded for later review. The child is directed to produce certain patterns of speech. During nasal endoscopy, patients are instructed to repeat key phrases that stimulate velopharyngeal closure, while a small, flexible endoscope views the lateral and posterior pharyngeal walls and the nasal surface of the velum. Both modalities provide useful information, although the velopharyngeal closure pattern is better assessed with nasendoscopy and may be more helpful in guiding further surgical intervention.^{30,31}

The next milestone in the treatment of patients with cleft lip and palate is often alveolar bone grafting. Traditionally, two-dimensional dental radiographs have been used to guide decision-making for this procedure. However, CT has proved superior to standard radiographs to characterize the alveolar defect volume preoperatively and the bone graft volume and resorption postoperatively.³² More recently, CBCT has emerged as the preferred imaging modality for this purpose given its decreased radiation dose, lower cost, and ease of use (Fig. 57-2).³³ CBCT has been shown to be highly accurate and precise for this indication when measured against a water-displacement method in an experimental model.³⁴ The CBCT field of view can be extended to evaluate calvarial bone as a potential donor site for maxillary grafting.³⁵ Furthermore, CBCT can be used to plan and evaluate osteointegrated dental implants after alveolar bone grafting; oral surgeons already use it routinely for this purpose.³⁶ CBCT scans should be reviewed by multiple members of a multidisciplinary team, because incidental findings of dental, airway, sinus, and ear abnormalities are common in these patients.³⁷

A subset of cleft palate patients will eventually require midface advancement. Although traditional cephalograms have been the mainstay of orthognathic planning, more recently, CT and CBCT have been used for quantitative 3D preoperative planning for midface advancement in adolescents with cleft lip and palate.³⁸

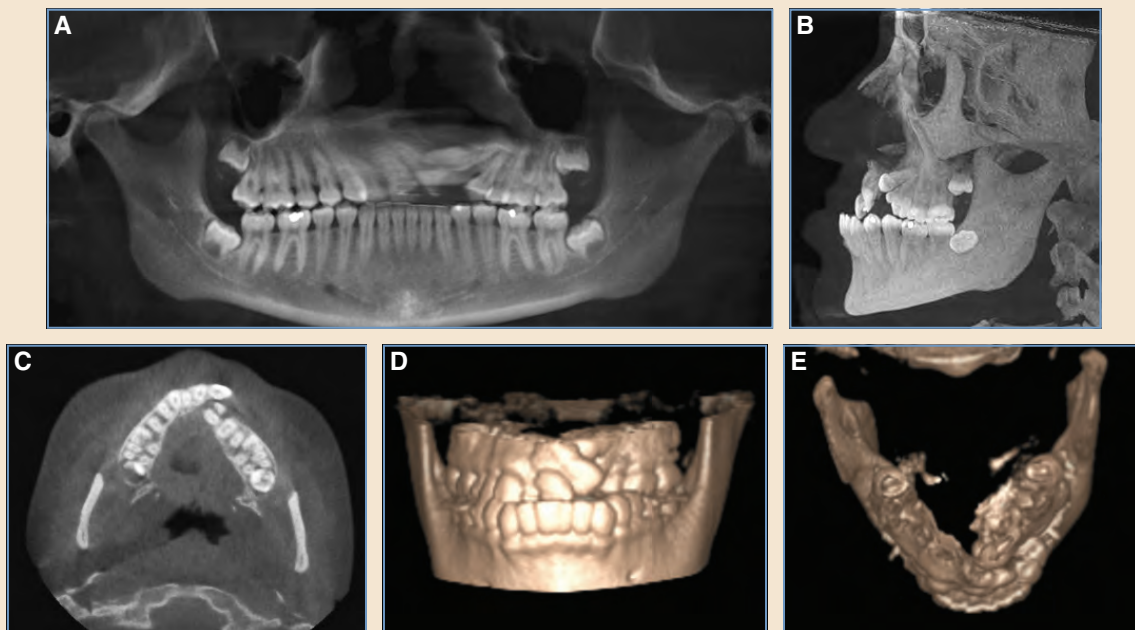

Fig. 57-2 CBCT scans of a 15-year-old female with a history of left cleft lip and palate. The scans were obtained for a preoperative workup before palatal expansion and alveolar bone grafting. The variety of image formats demonstrates the versatility and utility of CBCT. **A**, A traditional Panorex image generated from the CBCT scanner. **B**, A lateral cephalogram generated from the CBCT scanner, highlighting the patient's midface hypoplasia and negative overjet. **C**, An axial CBCT cut demonstrates well the patient's left-sided palatal collapse and alveolar bone deficit. The patient will require palatal expansion to reestablish the proper position of the maxillary arch, followed by alveolar bone grafting of the bony defect to prepare for an osteointegrated dental implant. **D** and **E**, An AP and worm's-eye view of 3D reconstructions generated using CBCT data.

Fig. 57-3 An arteriogram obtained during the preoperative embolization of an arteriovenous malformation (AVM) of the right face and right upper lip in an 11-year-old female. The AVM was first noted when the child was young and continued to enlarge over time. She underwent her first surgical resection (with incomplete excision) at 7 years of age at a different institution. **A**, A right common carotid artery angiogram showed blood supply to the AVM from the right facial artery. Fluoroscopy also clearly demonstrated venous drainage through the external jugular and retrograde through the angular vein. Such precise delineation of the vascular anatomy of a malformation can be very valuable information to guide operative planning and execution. **B**, An intraprocedure angiogram showed positioning of a sceptor balloon catheter within the distal right facial artery before embolization with Onyx. **C**, An angiogram performed after the embolization showed no blood flow to the lesion through the facial artery. Embolization achieved 100% occlusion of the AVM. The patient underwent excision of the vascular malformation with local tissue rearrangement for wound closure.

Vascular Anomalies

Vascular anomalies typically are diagnosed clinically; however, imaging is a useful adjunct in difficult diagnostic cases and for surgical planning. Multiple modalities, including ultrasonography, CT, CTA, MRI, MRA/MRV, and traditional fluoroscopic angiography, can be used to image vascular anomalies, depending on the location, the type of lesion, and preoperative planning needs.

Ultrasound imaging is often performed first, because it is free of radiation and does not require sedation. When combined with color Doppler ultrasonography, ultrasound imaging can provide information not only on structure but flow within a lesion.³⁹ However, MRI remains the standard for imaging vascular lesions given its superior ability to delineate soft tissues and fat signal suppression to clearly demarcate the anatomic boundaries of a lesion.⁴⁰ The use of MRA/MRV can help to identify a feeding artery and draining vein, similar to a traditional arteriogram and venogram, which can be important for surgical planning (Fig. 57-3). However, CT with contrast may prove more useful for lesions with osseous involvement.⁴⁰ Working closely with a pediatric radiologist will help surgeons to choose the optimal study.

Facial Trauma

Maxillofacial CT is the standard imaging modality for assessing pediatric patients with suspected facial fractures based on the history and clinical examination. The radiation dosage should be

Fig. 57-4 Axial and coronal CT slices of the facial bones show an entrapped medial orbital wall fracture. This 12-year-old male was kicked in the face during a martial arts class. He presented with slight restriction of superolateral gaze of his left eye with associated severe pain and diplopia. Mild bradycardia occurred with extreme lateral gaze. The patient underwent an exploration of the medial wall fracture through a transconjunctival incision. The medial rectus and orbital contents were reduced, and a resorbable plate was placed to repair the medial orbital wall.

kept as low as possible, although good data on the sensitivity of low-dose CT scan protocols for pediatric facial trauma are not available.⁴¹ Panoramic radiographs have some utility in evaluating mandibular fractures; however, interpreting plain radiographs in children is complicated by underdeveloped sinuses and tooth buds that can obscure fracture lines.⁴² Additional drawbacks of panoramic radiographs in patients with facial trauma include the need for patients to be motionless to obtain an adequate image, and, in those with spinal precautions who cannot be placed in the required supine position, it often cannot be performed.⁴³ CT scanning can help to detect subtle fractures of the mandibular condyle not seen on AP radiographs or panoramic radiographs, and it is also a sensitive modality for detecting fractures of the medial orbital wall and orbital floor⁴ (Fig. 57-4). 3D reconstructions can facilitate visualization of fracture patterns and surgical planning.

VIRTUAL SURGICAL PLANNING

CT-guided VSP is the newest and potentially most exciting evolving concept in pediatric imaging. It offers the opportunity for improved accuracy and decreased operative times for novice surgeons and can be a valuable tool for even the most seasoned surgeons in planning complex craniofacial reconstructions. Fig. 57-5 shows the use of VSP to correct a complex deformity after an earlier LeFort III midface advancement and subsequent counterclockwise rotation of the LeFort III segment. VSP was used to plan clockwise derotation of the LeFort III segment. Measurements for the planned movements at multiple reference points on the facial skeleton were determined through VSP (Table 57-1), and demonstrated on cephalometric projections. A LeFort I osteotomy will be performed at a later date to correct the occlusion.

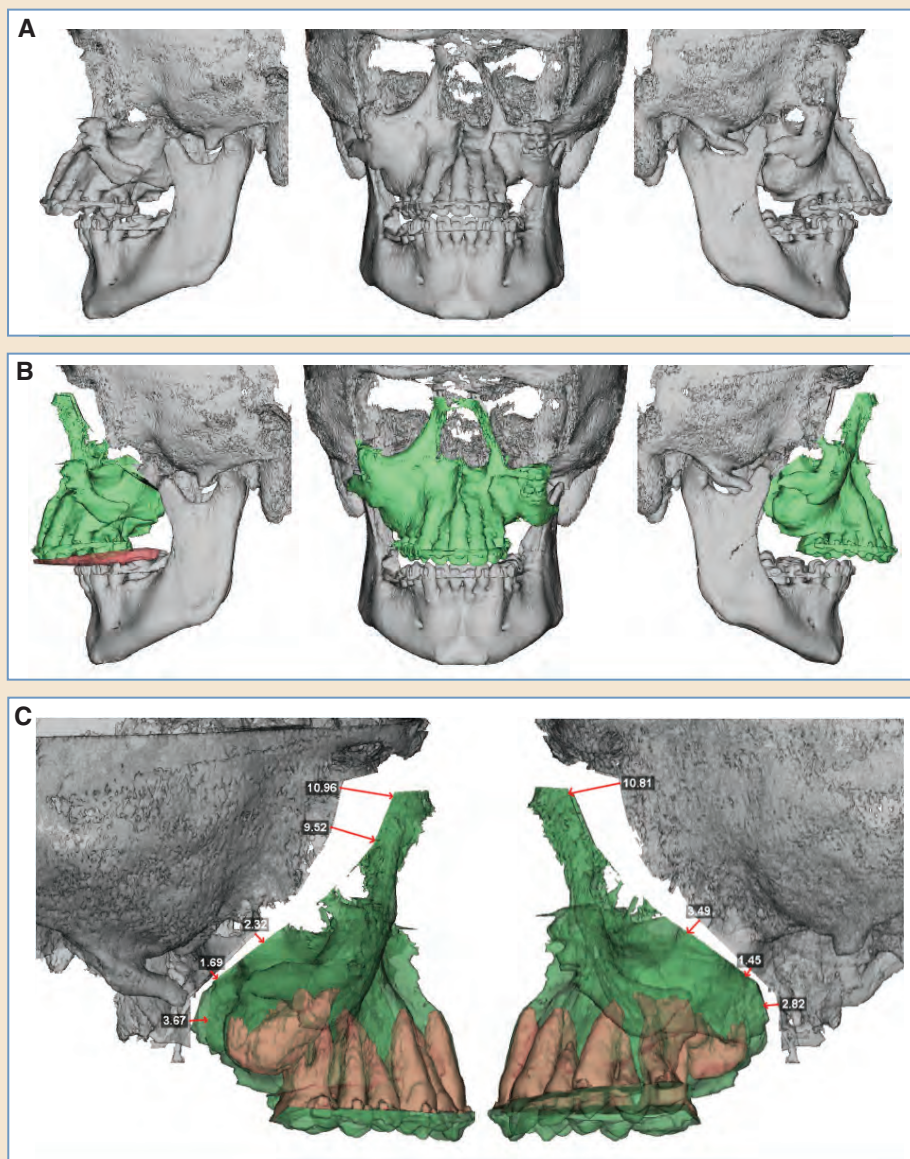

Fig. 57-5 VSP to correct a complex craniofacial deformity after a LeFort III midface advancement. **A**, 3D CT images show counterclockwise rotation of a LeFort III segment. **B**, VSP was performed to plan a clockwise derotation of the LeFort III segment. **C**, Cephalometric projections from the planned movement are demonstrated.

Table 57-1 Measurements for Planned Movements at Multiple Reference Points on the Facial Skeleton as Determined Through Virtual Surgical Planning

Point	Name	Anterior or Posterior	Left/Right	Up/Down
ANS	Anterior nasal spine	5.56 mm anterior	0.00	3.47 mm down
A	A point	4.46 mm anterior	0.00	3.56 mm down
ISU1	Midline of upper incisor	0.19 mm posterior	0.00	4.82 mm down
U3L	Upper left canine	0.05 mm posterior	0.00	2.58 mm down
U6L	Upper left anterior molar (mesiobuccal cusp)	0.17 mm anterior	0.00	0.09 mm down
U3R	Upper right canine	0.08 mm posterior	0.00	3.87 mm down
U6R	Upper right anterior molar (mesiobuccal cusp)	0.10 mm anterior	0.00	0.90 mm down
ISL1	Midline of lower incisor	2.62 mm posterior	0.06 mm left	4.13 mm down
L6L	Lower left anterior molar (mesiobuccal cusp)	2.43 mm posterior	0.07 mm left	1.97 mm down
L6R	Lower right anterior molar (mesiobuccal cusp)	2.81 mm posterior	0.08 mm left	2.27 mm down
B	B point	3.97 mm posterior	0.11 mm left	3.86 mm down
Pog.	Pogonion	4.93 mm posterior	0.14 mm left	4.02 mm down

Herlin et al⁴⁴ reported on the use of VSP for preoperative volumetric measurements and simulation, for design of cranial bone grafts, and for fabricating intraoperative cutting guides to treat patients with Treacher Collins syndrome. Shah et al⁴⁵ argued that the use of 3D CT scanning for preoperative simulation of frontoorbital advancement and fabrication of intraoperative cutting guides to be used for supraorbital bandeau osteotomies and manipulation can lead to more precise and reliable results in patients with metopic craniosynostosis. Furthermore, preoperatively planned frontoorbital advancements can be accurately achieved intraoperatively.⁴⁶ A recent multiinstitutional study has demonstrated an improved conformity of the operated supraorbital bandeau with ideal normative shape and a significant decrease in operative time using VSP and prefabricated templates to treat patients with metopic craniosynostosis.⁴⁷

CBCT also shows much promise for use in VSP. Measurements for LeFort I osteotomies using both traditional CT and CBCT have been shown to correlate well with each other and with direct physical measurement.⁴⁸ Katkar et al⁴⁹ showed high interobserver and intraobserver reliability for identification of cephalometric landmarks for orthognathic surgical planning using two of the most commonly used commercially available CBCT machines—Galileos (Sirona Dental Systems) and Next Generation iCAT (Imaging Sciences International)—in combination with Dolphin 3D software. Some authors have combined the use of traditional plaster models with CBCT-based VSP for orthognathic planning.⁵⁰ Facility with the use of VSP software and integration of these technologies into the preoperative planning of complex craniofacial and orthognathic procedures will increasingly become the norm for the coming generation of craniofacial surgeons.

KEY POINTS

- Clinicians must understand the indications, accuracy, advantages, and disadvantages of various imaging modalities to diagnose and treat pediatric patients with congenital or acquired malformations.
- CT is optimal for diagnosing bony abnormalities. CT visualization of soft tissues can be augmented by the addition of iodine-based contrast agents.
- CBCT allows faster image acquisition, with a lower radiation dose and lower cost, compared with traditional CT.
- MRI is often the optimal imaging modality for examining soft tissue.
- Despite low absolute risks, all efforts should be made to minimize the radiation dose to pediatric patients, including judicious use of imaging only when indicated and employment of proper equipment settings for pediatric craniofacial applications.
- For assessing patients with simple, single-suture, nonsyndromic craniosynostosis, CT imaging is not required, and the benefits may not outweigh risks. In contrast, 3D CT is a powerful tool for preoperative planning for syndromic craniosynostosis. Routine postoperative screening CT is not recommended for cranial vault remodeling.
- Multiview videofluoroscopy and video nasopharyngeal endoscopy are important adjuncts in assessing children with cleft lip and palate for velopharyngeal inadequacy. CBCT has emerged as the preferred imaging modality to evaluate these patients for alveolar bone grafting.
- Multiple modalities, including ultrasound, CT scan, CTA, MRI, MRA/MRV, or traditional fluoroscopic angiography can be used to image vascular anomalies, depending on the location, the type of lesion, and preoperative planning needs.
- Maxillofacial CT is the standard imaging modality for assessing pediatric patients with suspected facial fractures based on history and clinical examination.
- CT-guided VSP is the newest and potentially most exciting evolving concept in pediatric imaging, offering the opportunity for improved accuracy and decreased operative times for novice surgeons. It can also be valuable for more seasoned surgeons in planning complex craniofacial reconstructions.

Congenital Deformities of the Thorax and Chest Wall

*Jeremy P. Warner • Brian M. Christie • Dennis P. Lund
Michael L. Bentz*

Nuss Repair of Pectus Excavatum.

ongenital thoracic deformities consist of a handful of bony and cartilaginous defects that are usually present at birth and may persist into adulthood without intervention. The most common congenital thoracic deformities include Poland syndrome, pectus excavatum, pectus carinatum, and less frequently, Jeune syndrome and pentalogy of Cantrell. Although chest wall deformities in children were described as early as the fifteenth century, operative management of these defects did not bloom until the twentieth century.¹ Today, the considerations, techniques, and controversies regarding the management of these complex and difficult deformities are numerous. Most of the foundational thoracic, pediatric, and plastic surgery literature is still applicable today; however, some newer and evolving approaches exist.

POLAND SYNDROME

Poland syndrome is characterized by chest wall and upper extremity defects. Unilateral chest wall defects include partial or complete absence of the pectoralis major and minor muscles and their associated subcutaneous fat, hypoplasia of the ipsilateral breast or nipple, absence of axillary hair, absence of the natural anterior axillary border, and anomalies of the costal cartilages and anterior rib ends. Associated upper extremity defects include limb shortening, syndactyly and/or brachysyndactyly, carpal anomalies,² and hypoplasia/aplasia of the middle phalanges, which multiple authors have classified.^{3,4} Less frequently, patients have deformities of the serratus, infraspinatus,

latissimus dorsi, and external oblique muscles; dextrocardia⁵; or complete absence of the hand. The syndrome may also occur with congenital bilateral facial paralysis and the inability to abduct the globe, referred to as *Moebius syndrome*.⁶ Some patients have an associated hematopoietic malignancy or vertebral abnormalities. Although most cases are unilateral, bilateral symptoms are occasionally reported in the literature, with a widely variable phenotypic spectrum.⁷

History and Epidemiology

Poland,⁸ an English medical student, first described Poland syndrome in 1841, during the post-mortem evaluation of a convicted murderer. He noted that the patient had thoracic wall deformities, including a defect of the pectoralis major, confined to the musculature on one side of the chest.⁹ He also noted that in one hand the middle phalanges were absent in all fingers except the middle finger, and that the hand had webbing between the proximal phalanges and was shorter than the opposite hand. Previously, Lallemand in 1826 and Froriep in 1839 had described the absence of the pectoralis muscle without associated hand deformities.¹⁰ Poland syndrome may be underreported, because it is often undiagnosed. The prevalence is approximately 1 in 30,000 births. Estimating sex differences is difficult, because more women are presumed to present to surgeons for breast deformity correction. The deformity occurs most often on the right side.

Genetic and Etiologic Factors

The cause of Poland syndrome is unknown and controversial. Possible causes include an abnormal migration of embryonic tissues forming the pectoral muscles; hypoplasia of the subclavian, vertebral, and internal thoracic arteries; pharmacologic use during pregnancy; and in utero injury.¹¹⁻¹³ Poland⁸ noted during his landmark dissection that the internal thoracic arteries were smaller on the affected side. The vascular interruption theory is supported by studies of fetal vasculature development and the possible correlation between known structural abnormalities, including Moebius syndrome, Klippel-Feil syndrome, and Sprengel deformity. The hypothesis is that an insult to the developing vascular tree at a specific point in time¹⁴ during development of the pectoralis major sternocostal head, separation of the fingers, and chondrification of the middle phalanges³ will lead to predictable structural defects. Genetically, most cases appear to be sporadic; only a small number of reported genetic transmissions are consistent with an autosomal dominant gene, low penetrance, and a delayed mutation.^{11,13,15-18}

Functional Implications

The spectrum of chest wall abnormalities includes the following¹⁹:

- A normal thoracic cage with only pectoralis muscle absence
- Ipsilateral thoracic cage and sternal depression with or without contralateral sternal protrusion and rotation
- Ipsilateral rib hypoplasia without significant depression or protrusion of either the thoracic cage or the sternum
- Rib aplasia with depression of adjacent ribs and sternal rotation

Although all patients with Poland syndrome have absence or hypoplasia of the pectoral muscles, not all patients have bony abnormalities severe enough to require surgery. Whether the syndrome defects can be severe enough to compromise the cardiovascular system is controversial. Most cases are postpubescent females who present for cosmetic correction; however, some adolescents and males present with rib aplasia and resultant lung herniation or severe sternal depression that has caused thoracic constriction.

Cosmetic Implications

Most patients seen by plastic and thoracic surgeons are postpubescent females with rib abnormalities and breast hypoplasia/aplasia. Some surgeons advocate waiting to perform reconstruction until after breast maturity.²⁰ Definitive treatment of pubertal females is more difficult and must be individualized based on the patient's and parents' concerns.²¹

History and Assessment

Many patients with absent ribs are candidates for reconstruction, given the potential for lung herniation or susceptibility to thoracic trauma. Female patients merit intervention regardless of the functional considerations, because they invariably have cosmetic deformities by the time they seek surgical evaluation. Males can also have a significant cosmetic deformity. The deformity should be defined with CT imaging, preferably three-dimensional scanning. MRI can be helpful for further definition of the anatomy. These images are useful not only for defining the deformity, but also for indentifying surrounding anatomy for reconstructive options.

Treatment Options

Reconstructive considerations are focused on repairing the underlying bony structure, creating a symmetrical soft tissue structure, and creating an aesthetic breast (which may necessitate a mastopexy of the contralateral side). It has been shown that each of these reconstructive steps can be safely performed in a single operation.²² The bony structural layer is generally reconstructed by replacing the aplastic ribs on the affected side with contralateral rib grafts. The grafts can be split in half and used separately to replace multiple rib levels. Surgeons should not attempt to "build up the chest wall" with implant prostheses alone, because this does not correct the underlying structural defect. A sternal osteotomy and rotation may also be required, because the sternum can often be rotated toward the defect. Once the ribs are stabilized, they are covered with a synthetic graft to create a more natural contour. However, an autologous muscle flap achieves the same purpose without the potential complications of synthetic materials and may provide more bulk (particularly if innervation is maintained) and aid in the breast reconstruction. More recently, autologous fat grafting has been described for volume addition and contouring.^{23,24}

The latissimus dorsi muscle flap, supplied by the thoracodorsal vessels and nerve, is the primary flap used to reconstruct the chest wall in patients with Poland syndrome. This muscle provides sufficient tissue to improve symmetry with the opposite side and has been described to restore function as well.²⁵ A limited dorsal thoracic incision is made to mobilize the muscle from its origin. A second incision is made in the axilla to identify the vascular pedicle and to detach the muscle from its humeral insertion. The latissimus dorsi muscle is then transposed to simulate the deficient pectoralis muscle, to create an anterior axillary fold, and to cover the breast implant if a prosthesis is used or anticipated. Rarely, a patient has an associated ipsilateral latissimus muscle aplasia, and microsurgical transposition of the contralateral muscle may be performed.²⁶

Reconstruction options for the breast improved significantly with the advent of breast implant prostheses, particularly silicone and Silastic (Dow Corning) implants. Once the latissimus muscle is transposed, a prosthesis is inserted through the axillary incision. Some have advocated tissue expansion earlier in childhood, with expansion paralleling the growth of the contralateral breast.^{20,27,28} The expander is replaced with a permanent implant at maturity.

Japanese surgeons Ohmori and Takada²⁹ described their technique of reconstruction with and without silicone prostheses, associated with a myocutaneous flap. Two years later, Hester and

Bostwick²¹ described reconstruction for 11 patients using a latissimus dorsi muscle transposition with and without implants. This reconstruction has been modified by twisting the muscle flap between its transposed origin (between the deltoid and the biceps) and its insertion, a technique that creates a fuller anterior axillary fold.³⁰ Although some surgeons believe mild to moderate deformities can be reconstructed without skeletal reconstruction, most agree that it makes reconstruction difficult and that aplastic ribs, in particular, should first be corrected.^{31,32}

Surgical Technique

An incision is placed along the anterior border of the latissimus, or in female patients, horizontally in the bra line, depending on the patient's preference and required chest wall access. Skin is then elevated off the latissimus dorsi, and medial, lateral, and inferior attachments of the muscle are divided. The humeral attachment is divided, completely freeing the muscle as an island on its neurovascular pedicle. A tunnel is dissected anteriorly to connect with an anterior chest pocket that is dissected through an inferolateral submammary incision. The muscle is then passed through the tunnel and placed in the anatomic space normally occupied by the pectoralis muscle. Inferiorly, the latissimus is sutured to the chest wall fascia at the level of the inframammary crease. Medially, the muscle is sutured to fascia overlying the lateral sternum, and superiorly, it is sutured to the clavicular portion of the pectoralis major. The anterior axillary fold is created by suturing the detached insertion of the latissimus dorsi to the periosteum of the humerus, just below the insertion of the clavicular head of the pectoralis major. After an implant is placed under the latissimus, sutures are secured laterally to prevent lateral displacement. Care is required to ensure that blood flow to the vascular pedicle is not compromised.

Postoperative Care

Patients are instructed not to participate in contact sports for 6 months.

Treatment Outcomes and Complications

Long-term results are excellent with the use of the reconstructive techniques described previously and autologous tissue transfer. Major complications include damage to the latissimus dorsi neurovascular bundle and pneumothorax. An intact nerve maintains muscle bulk but can be associated with muscle overactivity. Deliberate division of the thoracodorsal nerve is controversial.

PECTUS EXCAVATUM

Pectus excavatum (funnel chest), a concavity of the anterior chest wall, is the most common congenital chest wall deformity. This variable deformity is a result of abnormal costal cartilage position and growth, leading to posterior angulation of the cartilages below the manubrium, posterior curvature and displacement of the sternum, and a diminution of the AP diameter of the thoracic cage (Fig. 58-1).

History and Epidemiology

Pectus excavatum was first documented in 1594. In 1949 Ravitch³³ from Johns Hopkins University best described the condition. He noted the characteristic sternal depression, rounded and sloped shoulders, a slight dorsal kyphosis, a prominent potbelly, and retraction of the sternum on deep inspiration. The association with cardiopulmonary dysfunction is controversial. Other associations include Marfan syndrome, scoliosis, hypomastia, cardiac murmurs, and ECG changes.³⁴

Fig. 58-1 Pectus excavatum in an adolescent.

Most cases are identified in early infancy. The depression can become more pronounced as patients grow, although some resolve. The male/female ratio is 3:1.

Genetic and Etiologic Factors

The most plausible cause of pectus excavatum is overgrowth of abnormal costal cartilage, which depresses the sternum in an often-rotated position. The initial theory of pectus excavatum, supported by multiple authors, was that of a shortened substernal tendon pulling the sternum posteriorly during growth.^{35,36} Ochsner and DeBakey³⁷ discounted this theory in 1939, proposing their “abnormal cartilage” theory. Feng et al³⁸ have substantiated this theory in their biomechanical, morphologic, and histologic review,³⁸ although it has been challenged.^{39,40} However, the cartilage theory describes only the gross mechanical physiology. A number of pathogenetic hypotheses have been suggested, but the exact cause leading to the deformity is not known. A positive family history has been noted in up to 43% of cases.^{41,42}

Preoperative Assessment

Care is most often sought by the adult patient (or by parents for their young child) for cosmetic concerns, although some patients may have symptomatic respiratory problems. The effect of a chest concavity deformity on the cardiopulmonary system is controversial, as shown in detailed reviews.^{43,44} Although it seems intuitive that compression of the mediastinum by a depressed sternum would lead to cardiovascular and pulmonary impairment, both anecdotal and scientific evidence have failed to concretely show improvement in status after surgical repair.⁴⁵⁻⁴⁷ Recent studies have shown that deterioration in pulmonary function may be present after operative correction.^{44,47,48} More recently, Malek et al⁴⁹ conducted a meta-analysis of eight studies meeting strict inclusion criteria and that suggested cardiovascular function improved. These results have been challenged.^{50,51} Nonetheless, several studies indicate a significant improvement in body image, perceived ability for physical activity, and subjective patient satisfaction.^{46,52-55} The basis for such controversy is most likely a result of the complex measures used to evaluate cardiac and pulmonary function, the variability in parameters between individuals,⁴⁰ and the variability

in study designs.⁴⁷ Preoperative cardiopulmonary testing, such as pulmonary function tests and ECG, may be useful in patients with severe mediastinal compression.

Complex radiographic studies are not needed for a pectus repair itself, although CT scans have been used as an indication guideline in some series.⁵⁶ Appropriate consultation should be sought in patients with associated anomalies, including Marfan syndrome and scoliosis. Metal allergy ranges from 2% to 15% and may warrant preoperative testing if the use of titanium constructs is considered, as in a Nuss procedure.^{54,57} The patient age for pectus reconstruction is based on each case, although the age at operation appears to be trending upward nationally.⁵⁸ The reasons for performing early surgery include technical ease and less complex reconstruction. However, because the operation is performed for cosmetic appearance in most cases, some argue that the child should make this decision when older. Moreover, after a reconstruction, the chest wall deformity can recur as a child grows.

Treatment Options

The initial surgical treatment for pectus excavatum in the early 1900s consisted of complete resection of the deformed ribs and sternum, which led to paradoxical breathing, an unprotected heart, and a poor cosmetic result.⁵⁹ Subsequently, resection of only the rib ends with elevation of the sternum evolved. In this early technique, traction sutures were placed through the skin and suspended above the patient's bed. Ochsner and DeBakey³⁷ pioneered the common technique of cartilage resection with sternal support. Similar to earlier methods of fixation, they used a metal band around the sternum that was connected to rubber bands attached to an external plaster cast.

Currently, three major options are available to patients with pectus excavatum:

1. Soft tissue or prosthetic augmentation
2. Both open sternal or costal cartilage manipulation and resection with internal or external sternal support (see Fig. 58-2)
3. The innovative minimally invasive technique devised by Nuss et al,⁵⁹ which requires neither a cartilage incision or resection

Soft Tissue or Prosthetic Augmentation

Soft tissue and prosthetic reconstruction involve camouflaging the defect with a silicone or Silastic implant. Initially, these implants were placed subcutaneously, but they are now placed submuscularly to prevent anterior displacement.⁶⁰⁻⁶³ They may also be fixated with a synthetic patch. This option is best for patients who are fully grown and have no subjective physiologic concerns (the previously mentioned cardiopulmonary concerns).

Open Sternal or Costal Cartilage Manipulation and Resection With Internal or External Sternal Support (Ravitch Procedure)

Open sternal reconstructions are generally modeled after the Ravitch procedure, which includes excision of costal cartilages in a subperichondrial plane for the full length of the deformity, separation of the intercostal bundles from the sternum, and an anterior sternal osteotomy for elevation without external fixation.³³ The modified Ravitch procedure involves removal of three to four bilateral overgrown cartilages, with anterior repositioning of the sternum through a posterior transverse osteotomy with internal fixation or support. The sternum is predominantly supported by the lower ribs (Fig. 58-2).

Generally, a temporary support bar or wire is inserted behind or through the sternum for support. Potential modifications to this procedure are numerous, and nearly all employ bilateral resection of abnormal cartilage, a sternal osteotomy, and sternal fixation in the corrected position. They generally differ with respect to the method of sternal fixation. Examples of these

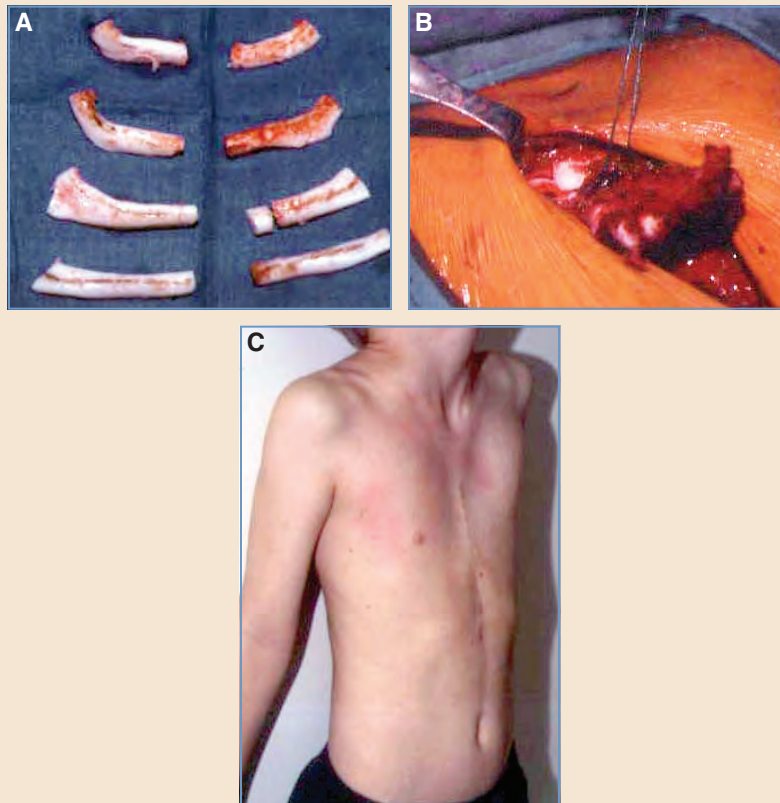

Fig. 58-2 Surgical repair of pectus excavatum. **A**, A subperichondrial costocartilage excision. **B**, Circumferential suture fixation with retrosternal cartilage graft incorporated into the posterior osteotomy site. **C**, The patient is shown postoperatively.

modifications include the placement of a permanent vascularized rib strut behind the sternum for support,⁶⁴ the use of a bioabsorbable strut made from poly-L-lactide,⁶⁵ resection of the lower four or five ribs bilaterally and placement of a steel strut,⁶⁶ the insertion of rigid plates for sternal fixation,⁴⁶ a sternal turnover with stabilization and contour,⁶⁷⁻⁷⁰ rib resection with a presteral suspension support bar,⁷¹ and maintenance of the sternal position with transcutaneous wires connected to an external brace.⁷²

Endoscopic Sternal Repair and the Nuss Procedure

Endoscopic repair is on the horizon.⁷³ A thoracoscope and surgical instruments are inserted through small, 3 mm stab wounds to transect the rib cartilages, to place a retrosternal strut, and to perform an anterior wedge osteotomy. The Nuss procedure corrects sternal angulation without resecting costal cartilages. Nuss et al⁵⁹ described this procedure in a 10-year review published in 1998. It involves inserting a convex steel bar inserted through small, bilateral thoracic incisions and then under the sternum. Modifications to this procedure have been described, including a subxyphoid approach with central fixation to the costal margins.⁷⁴ Multiple comparisons of surgical techniques, primarily between the modified Ravitch procedure and the Nuss procedure, have been made.⁷⁵⁻⁷⁷ They demonstrate no clear difference in outcomes, including success rates, major complications, and patient satisfaction.

The Nuss Procedure

In a Nuss procedure, a thoracic epidural catheter is placed preoperatively for postoperative pain relief. Whenever possible, this is done with the patient awake before the induction of anesthesia to optimize placement. The patient is brought to the operating room, and general endotracheal anesthesia is induced. Prophylactic antibiotics that provide good coverage of skin flora are given. The patient is positioned symmetrically on the operating room table, with shoulders abducted to 90 degrees and elbows bent upward to 90 degrees. This allows bilateral access to the lateral chest wall. A sheet or blanket is rolled and placed longitudinally behind the center of the back so that the shoulders fall backward slightly. The neck, chest, and upper abdomen are prepared with a sterile cleaning solution; the preparation continues down to the operating room table on both sides of the chest. The entire prepared area should be accessible after the patient is draped.

The deepest part of the deformity is marked, and marks are also made in line with this point on either side of the sternum—bilaterally at the midclavicular lines and at the midaxillary lines. The line described by these marks must be square with the patient's chest. If the deepest point of the sternum is inferior to the xiphoid, the lower end of the sternum is marked.

A pectus bar template is chosen to develop the mold for the pectus bar. (All instrumentation for this procedure is available from W. Lorenz Surgical.) The ends of the chosen aluminum template, once shaped, will extend from one midaxillary line to another. The template is molded to the patient's chest wall laterally, leaving the central portion nearly straight. The corresponding stainless steel pectus bar is bent to the same shape using a bar-bending tool. The very ends (2.5 cm) of the bar should not be bent. With the ends straight, the side-stabilizing crosspieces can be properly seated.

Transverse incisions measuring 2.5 cm each are made in the lateral chest wall bilaterally, centered on the midaxillary lines in the plane previously marked. Superior and inferior skin flaps on the serratus muscle fascia are developed, allowing plenty of room for the stabilizing crosspieces. Subcutaneous tunnels on the muscle fascia are then developed from the lateral incisions to the highest ridges of the anterior chest, usually at about the midclavicular lines. A 30-degree thoracoscope is introduced into the left chest, and the chest is gently insufflated with CO₂ (to 5 cm H₂O) to help collapse the lung. This scope is used to view the thoracic organs while the tunneling device is passed behind the sternum.

A tunneling device, or introducer, is passed from the patient's right side through the subcutaneous tunnel to the anterior chest. The introducer enters the chest just medial to the highest ridge through the selected intercostal space. As the introducer enters the chest, it is rotated 180 degrees to hug the back of the sternum as it is passed behind the sternum toward the left chest. This is done while observing through the thoracoscope, and it should be performed very carefully, because this is the most dangerous part of the procedure. The surgeon must stop and try another path if any resistance is met as the tunneler is advanced behind the sternum. Once the tunneler is safely in the left chest, it is again passed anteriorly just medial to the highest ridge into the left-sided subcutaneous tunnel through the appropriate intercostal space. The tip of the introducer is advanced through the subcutaneous tunnel out to the left lateral chest wall incision. Three sizes of introducer are available, depending on the size of the patient.

A double length of umbilical tape is threaded through the eye on the end of the introducer. The introducer is withdrawn back through both sides of the chest and out through the right lateral incision, bringing the tapes with it. The properly curved pectus bar is securely attached to one of the tapes, leaving the second tape as a backup, should the first tape break during passage of the bar. Using traction on the tape from the patient's right side, while observing through the thoracoscope, the pectus bar is advanced upside down through the pathway created. Once the bar has passed through the tunnels and is exiting both lateral incisions, it is turned over using the bar-turning tool. This pushes the sternum and anterior chest wall into the desired position.

Once the bar is properly positioned, the chest wall is corrected. If the correction is deemed to be adequate, the stabilizing pieces can be placed. However, if the correction is not ideal, it may be necessary to place a second bar. This most commonly occurs in older patients who have a lengthy deformity involving both the upper and lower portions of the sternum. If needed, a second bar is typically placed two intercostal spaces above or below the first bar.

Once the correction is adequate, lateral stabilizing crosspieces are placed on both sides of the pectus bar. Although the manufacturer states that only one stabilizer may be needed per bar, bar rotation has been a frequently reported complication; therefore we recommend using two stabilizers per bar. The bar must be derotated to place the stabilizers, but the bar is then rotated once again into the desired position. The bar should sit in the channels in the stabilizers, with the flat side of the stabilizer facing the chest wall. The stabilizers are secured to the chest wall so that they reside at least 1 to 2 cm from the end of the bar. The stabilizers are secured to the pectus bar and to the chest wall using two No. 4 stainless steel wires on either side, medial and lateral to the stabilizer. The stabilizers are then secured to the chest wall using 1-0 Prolene sutures above and below each side of the bar. Large Valsalva breaths are given to evacuate the pneumothorax.

The wounds are inspected, and hemostasis is meticulously confirmed. The subcutaneous tissue of the lateral incision is securely closed with absorbable suture. The wounds are closed with subcuticular absorbable suture and occlusive dressings. A chest radiograph is obtained in the operating room to assess for pneumothorax and to document the alignment of the bar.

Postoperative Care

Postoperatively, pain is controlled with a combination of epidural and intravenous analgesia. Older children and those with a more rigid chest wall have more postoperative pain. Epidural analgesia for 3 to 5 days postoperatively reduces the need for narcotics and the attendant risks associated with their use. Incentive spirometry is actively encouraged, and careful early ambulation is initiated. Patients are weaned from epidural analgesia when tolerated and transitioned to oral pain medications. They are discharged once they are ambulating and eating and pain is well controlled with oral analgesics. A postoperative bowel program is almost always necessary.

Activity is limited for the first 6 weeks after surgery. Good posture is encouraged, and we frequently employ a figure-of-eight clavicle fracture brace to encourage good posture. This is worn night and day for the first 6 weeks. Generally, the pectus bar remains in place for 3 years.

After 3 years, the patient is returned to the operating room. With the patient under general anesthesia, the entire chest is again prepared and draped, allowing access to both lateral chest wall incisions. The previous incisions are opened, and the ends of the pectus bar and the attached stabilizers are exposed and dissected free. The permanent sutures and previously placed wires are removed. A thick scar and even some bony formation around the stabilizers are often present. The stabilizers are removed from the bar. Using the bar-removal and bar-bending tools, the ends of the bar are carefully straightened enough to allow the bar to slide out of one or another of the incisions. Once the bar is removed, a local anesthetic is injected, and the soft tissues and skin are closed in layers with absorbable sutures. This procedure can frequently be performed on an outpatient basis.

Treatment Outcomes and Complications

Haller et al⁵⁶ reported a 95% success rate in 664 patients and 5% mild to moderate recurrence. Kelly et al⁵⁵ reported a similar success rate in 1215 patients, with a 1.4% recurrence rate. Sacco Casamasima et al⁷⁸ reported similar success results in 336 patients, with modifications to the Nuss procedure reducing recurrence rates to 1.7%. Long-term results after a Nuss procedure have remained excellent over 10 years (96.5%), with removal of the support bar in most patients, and an incidence of recurrence of 3%.⁵⁹ The outcome for pectus excavatum repair (see the accompanying video) is

generally excellent when the cartilages are properly resected and the sternum elevated and fixated. According to one study,⁷⁹ complications included wound infection, fluid collection, fracture, migration of hardware, costal cartilage protrusion, pneumothorax, and bar displacement, which was the most common complication. The mortality rate was very low (0.5%).

PECTUS CARINATUM

Pectus carinatum is an anterior convexity of the chest wall and sternum. It is the second most common anterior chest wall deformity after pectus excavatum. Some consider it the antithesis of pectus excavatum. The pathogenesis of both deformities is attributed primarily to the overgrowth of the costal cartilages, with both anomalies described as different manifestations of the same process.^{80,81} If the overgrown cartilages push the sternum inward, pectus excavatum develops, whereas, if the sternum is displaced forward, the result is pectus carinatum.

History and Epidemiology

Pectus carinatum accounts for 6% to 22% of all deformities of the chest wall; the incidence of a familial deformity in these patients is 26% to 33%. The prevalence is estimated as 0.6% to 0.7%.^{82,83} Unlike pectus excavatum, these deformities are usually not noticed in childhood and become apparent during rapid pubertal growth. The male/female ratio is 4:1.⁸⁴ Three categories of morphologic presentation of pectus carinatum are described, based on the location of the maximal convexity along the sternum: (1) keel chest (chondrogladiolar prominence), (2) pouter pigeon breast (chondromanubrial prominence), and (3) lateral pectus carinatum. Keel chest is characterized by sternal elongation and inferior sternal xiphoid prominence. It is commonly associated with bilateral depression of the lower costal cartilages. Pouter pigeon breast has a more superior manubrial sternal prominence with a reduction of the normal angle of Louis, creating a depression of the lower two thirds of the sternal body. Lateral pectus carinatum has a unilateral overgrowth and protrusion with rotation of the sternum to the contralateral side. Associated abnormalities include scoliosis, Marfan syndrome, Poland syndrome, Morquio disease, Noonan syndrome, LEOPARD syndrome, and neurofibromatosis.

History and Assessment

Similar to patients with pectus excavatum, patients with pectus carinatum present for cosmetic correction of their chest wall deformity, because many have a distorted body image.^{85,86} The workup is similar for both. Bronchopulmonary changes have been described in patients with pectus carinatum.^{87,88} Much like pectus excavatum, no concrete evidence shows an improvement in cardiopulmonary status after surgical correction, but subjective improvement has been reported.⁷²

Nonsurgical and Surgical Treatment Options

Nonsurgical options for patients with pectus carinatum seeking cosmetic correction consists of bracing. Haje and Bowen⁸⁹ first described the use of bracing for these patients in 1976 and published long-term results in 1992. Patients usually wear a brace for most of the day for 4 to 8 months, and then transition to a more relaxed schedule. Recent literature suggests that this form of treatment is increasing in popularity.⁹⁰ Recently, Martinez-Ferro et al⁹¹ reported a high success rate among compliant patients.

Multiple surgical approaches have been described for correction of the pectus carinatum deformity. Recently, Schaarschmidt et al⁹² described a minimal-access hybrid technique using endoscopic assistance. Del Frari and Schwabegger⁹³ described a muscle-splitting technique involving the placement of bioabsorbable plates and postoperative bracing. Fonkalsrud⁹⁴ reported a progressive decrease in costal cartilage resection over his 37-year experience, with maintenance of consistent cosmetic results. Kálmán⁹⁵ described a correction procedure analogous to the Nuss procedure for excavatum repair that required neither a cartilage resection or a sternotomy, although long-term results have not been evaluated.

Correction of keel chest pectus carinatum consists of a bilateral resection of the abnormal costal cartilages along the entire extent of the deformity, a transverse sternal osteotomy at the upper end of the deformity, and fracture of the posterior lamina, leading to depression of the sternum. Surgical access is similar to that of open Ravitch-type excavatum repairs, although commonly less extensive. The xiphoid process is left in situ undisturbed and scored posteriorly or partially removed. The sternal construct is secured by suture fixation to the rectus abdominis muscle. The pectoralis muscles are advanced and reunited presternally. A light compression dressing further secures the corrected sternal position.

The steps to correct a pouter pigeon breast are similar to those described for repairing pectus excavatum. The deformed costal cartilages are resected bilaterally, the prominence of the manubriosternal junction is flattened using an osteotome, a transverse V-shaped sternotomy is made at the vertex of the angle of Louis (with a second linear osteotomy at the level of the deepest sternal depression), and the sternum is bent appropriately and detached from its perichondrial and mediastinal attachments. Mesh can be placed behind the sternum for support. The sternum is then covered with pectoralis muscles sutured together presternally. The xiphoid process is reattached to the sternum.

The correction of lateral pectus carinatum depends on the extent of cartilaginous overgrowth. If only a few unilateral cartilages are involved, an incision can be made over them and the protuberance removed subperichondrially. The resection should be more radical than conservative. If cartilage overgrowth is extensive, a short parasternal segment of the cartilages on the contralateral side should also be resected.

Treatment Outcomes and Complications

Surgical treatment outcomes are excellent regardless of the method used. Complications are similar to those for pectus excavatum repair and are uncommon. Recurrence is associated with conservative resection. Growth and development of the chest wall are usually normal after the repair.

JEUNE SYNDROME

The rare thoracic deformity known as *Jeune syndrome* is characterized by skeletal dysplasia, including a narrow immobile thorax and micromelia, with respiratory and renal manifestations. Respiratory manifestations vary widely from respiratory failure and death in infancy to a latent phenotype without respiratory symptoms.

History and Epidemiology

In 1955 Jeune et al⁹⁶ reported two siblings with severely narrowed thoraxes. They explained their condition as familial asphyxiating thoracic dystrophy. The incidence of Jeune syndrome is estimated at 1 in 100,000 to 1 in 130,000 live births. Most patients die in infancy and early childhood; very few mature to adulthood.

Genetic and Etiologic Factors

The genetic pattern of Jeune syndrome is autosomal recessive; 45% of cases are reported in siblings. Virtually all cases are diagnosed by 6 months of age.⁹⁷ Genetic counseling is indicated. The parents of a child affected with Jeune syndrome are obligatory carriers and have a 25% chance of having a second afflicted child. The bony abnormalities are thought to result from in utero disturbance of endochondral bone formation.

Functional Implications

The narrow thorax is motionless, and respiration is entirely abdominal. Considerable supraclavicular and suprasternal retraction of the intercostal space may be present on inspiration. The anatomy includes a long, narrow, and abnormally small thorax with reduced thoracic cage capacity and hypoplastic lungs.⁹⁸ The thorax is narrow transversely and sagittally. The fourth through ninth ribs bend inward, usually at the costochondral junction. The small thorax usually improves with age for those who survive early childhood. The limbs have variable micromelia and short digits with bulbous terminal phalanges and occasional postaxial polydactyly of the hands and feet.

Other associated anomalies include retinal degeneration, intestinal malabsorption, renal failure, hypertension, liver abnormalities, heart disease, and pancreatic abnormalities.⁹⁹

Nonsurgical and Surgical Treatment Options

Supportive medical care may involve mechanical ventilation of the lungs, which is urgently implemented in the most severe cases. In less severe cases, it may be required after several bouts of pneumonia with subsequent ventilatory failure. Phenotypically, this latent group of patients has a chest wall configuration identical to that of neonates with early, severe problems.¹⁰⁰ However, their respiratory compromise is mild and rarely requires surgical correction. Surgery is indicated only in the most severe cases, in whom failure to intervene will result in progressive pulmonary damage and death.

Chest reconstruction requires preoperative planning with CT scans and plain chest radiographs. Pulmonary function and renal function should be evaluated before general anesthesia is induced.¹⁰¹ Thoracic reconstruction is performed by a longitudinal sternotomy to increase intrathoracic volume and fixation with bone grafts, a methylmethacrylate prosthesis, steel struts, or rib grafts.^{102,103} In one technique, horizontal K-wires are placed across the sternal defect, coated with methylmethacrylate, and linked vertically with additional acrylic¹⁰⁴ (Fig. 58-3). A methylmethacrylate prosthesis can be made before surgery, thus saving considerable anesthesia time. The prosthesis supplies support along the entire length of the sternal edges to prevent herniation of the heart and lungs. It may be replaced with a larger prosthesis as the child grows.

Davis et al¹⁰⁵ described lateral thoracic expansion for correction of asphyxiating thoracic dystrophy in patients with Jeune syndrome. This procedure is performed without splitting the sternum. The chest wall is enlarged by dividing the ribs and underlying tissue in a staggered fashion to ensure that either rib or periosteum covers the lung. Titanium plates maintain the rib separation. Waldhausen et al¹⁰⁶ have expanded the vertical expandable prosthetic titanium rib (VEPTR) procedure for application in Jeune patients. Vertical titanium struts are inserted,

Fig. 58-3 A, An intraoperative view of a patient with Jeune syndrome undergoing placement of an acrylic-reinforced methylmethacrylate K-wire strut. B, An immediate postoperative view of a Jeune syndrome repair.

attached to the ribs and transverse processes of the spine, and progressively expanded to increase the intrathoracic volume. Although the vertical expandable titanium rib procedure has been successful in patients with pediatric thoracic insufficiency from other causes, its use in Jeune syndrome patients has led to controversial improvements in pulmonary function, and long-term results of this approach are not yet available.¹⁰⁶

Kikuchi et al¹⁰⁷ modified the Nuss technique, described previously, for use in older patients with more mild forms of Jeune syndrome. Muthialu et al¹⁰⁸ reported using a single-stage bilateral treatment involving titanium plating for rapid expansion, although long-term results have not been evaluated. Conroy et al¹⁰⁹ published a case of sternal distraction for severe neonatal Jeune syndrome, which was reported to be successful at 8 months.

In addition to surgical correction of the chest deformity, dialysis and, often, renal transplantation are indicated for renal failure.

PENTALOGY OF CANTRELL

Cantrell syndrome,¹¹⁰ also known as *pentalogy of Cantrell*, consists of the following anomalies:

- An anterior diaphragmatic hernia
- An upper omphalocele
- Ectopia cordis
- Intracardiac anomalies
- A bifid sternum

Cantrell syndrome often presents as an incomplete constellation, with hallmark anomalies of an omphalocele and ectopia cordis. Various other anomalies have been described in association with Cantrell syndrome, including a cleft lip/palate, hydrocephalus, encephalocele, limb defects, gallbladder anomalies, and polysplenia.¹¹¹ Skeletal and dermatologic manifestations have been reported.¹¹²

History and Epidemiology

Cantrell et al¹¹⁰ first described this condition in 1958 at Johns Hopkins Hospital. It is a rare syndrome; the prevalence is estimated at 5.5 in 1 million live births.¹¹³ The survival rate is less than 40%, and early surgical intervention does not necessarily improve outcome.^{114,115}

Genetic and Etiologic Factors

The cause of pentalogy of Cantrell is not known. Cantrell et al¹¹⁰ originally postulated a developmental failure of lateral mesoderm at about 14 to 18 days of gestation (before or immediately after the differentiation of the primitive mesoderm into the splanchnic and somatic layers), with failure of development of the transverse septum of the diaphragm and failure of migration of the paired mesodermal folds of the upper abdomen ventromedially. Carmi and Boughman¹¹³ hypothesized that pentalogy of Cantrell is the most severe expression of a variety of anomalies involving the development of the ventral midline, accounting for the variable and often incomplete phenotypic presentations.

Functional Implications

Cardiac anomalies include ventricular septal defect, atrial septal defect, tetralogy of Fallot, left ventricular diverticulum, anomalous pulmonary venous return, and patent ductus arteriosus.^{112,113} Sternal malformations are very diverse, including a bifid sternum, absence of the xiphoid process, absence of the lower two thirds, and incomplete formation of the lower half of the sternum.¹¹²

Nonsurgical and Surgical Treatment Options

Pentalogy of Cantrell can often be diagnosed with prenatal ultrasonography within the first trimester of pregnancy, when an omphalocele can frequently be identified. The rest of the pentalogy should be ruled out concurrently and includes the use of prenatal ECG.^{116,117} MRI has been suggested for prenatal and postnatal evaluation to detect more subtle fetal anomalies.¹¹⁸⁻¹²⁰

The surgical treatment of pentalogy of Cantrell is individualized as a result of the variability of defects, and timing depends on a patient's specific defects and the urgency of intervention because of pending respiratory or heart failure.^{115,121} Incomplete and complete pentalogy has been treated both in a single stage and in a staged approach.^{115,122-124} The omphalocele is typically closed as soon as possible. Intracardiac defects are corrected in accordance with the specific defect and its indications. The order of closure of abdominal wall defects and intracardiac defects depends on the size of the abdominal defect and the stability of the cardiac defect; large abdominal wall defects may need to be closed before cardiac surgery, whereas smaller abdominal wall defects can be repaired afterward. However, cardiac lesions that are sufficiently complex may need to be corrected first.¹¹² Sternal clefts are often closed in the neonatal period with sternal banding and autologous tissue (when sufficient); alloplastic mesh or plating can be placed until sufficient autologous material is available.^{125,126} The diaphragm is often plicated, and the heart is returned to the thoracic cavity by fixation of the pericardium to the ventral side of the diaphragm.¹²⁷

KEY POINTS

- Patients with Poland syndrome may have thoracic cage, sternal, muscle, and breast deformities requiring bony reconstruction, the creation of a symmetrical soft tissue, and reconstruction of an aesthetic breast.
- Pectus excavatum is, at a minimum, a cosmetic deformity that can be corrected surgically with an implant and soft tissue augmentation or with bony manipulation using an open, endoscopic, or minimally invasive technique.
- Pectus carinatum can involve the lower anterior chest (keel chest), the upper anterior chest (pigeon chest), or the lateral chest (lateral pectus carinatum). Surgical correction requires bony resection, stabilization, and soft tissue recontouring.

39. Nakaoka T, Uemura S, Yano T, et al. Does overgrowth of costal cartilage cause pectus excavatum? A study on the lengths of ribs and costal cartilages in asymmetric patients. *J Pediatr Surg* 44:1333, 2009.
40. Nakaoka T, Uemura S, Yoshida T, et al. Overgrowth of costal cartilage is not the etiology of pectus excavatum. *J Pediatr Surg* 45:2015, 2010.
This article and the article preceding it provided a substantial challenge to the concept of costal cartilage overgrowth as the pathogenesis for pectus excavatum. The first article investigated the length of the ribs and cartilage in patients with asymmetrical pectus excavatum. The ribs and cartilage of the side with more severe depression were actually shorter than those on the contralateral side, suggesting that overgrowth may not be the cause. The second article compared the fifth and sixth ribs and costal cartilage in patients with pectus excavatum and in healthy controls; no significant difference was revealed.

This review article assessed the debate regarding the effects of pectus excavatum repair on the cardiopulmonary system. Conflicting studies tended to use different measurement systems, leading to difficulty in interpreting results. The authors concluded that further studies were needed to define the relationship between pectus excavatum and cardiac function.

Congenital Defects of the Abdominal Wall

Lee W.T. Alkureishi • Lawrence J. Gottlieb

ongenital defects of the abdominal wall comprise a large spectrum of deformities, ranging from small umbilical hernias to giant omphaloceles and eventration associated with gastroschisis. Also included is a group of patients with varying degrees of congenital abdominal wall laxity, such as those with prune belly syndrome and megacystic microcolon intestinal hypoperistalsis syndrome. These conditions have a wide variety of causes, associated morbidities, and management.

ANATOMY

An umbilical hernia is a central abdominal wall defect involving the linea alba, with persistent herniation of intraabdominal contents into the umbilical stalk (Fig. 59-1). The skin overlying the hernia is intact.¹

An omphalocele, or exomphalos, is a midline defect of the ventral abdominal wall, resulting in extrusion of intraabdominal contents covered by a membrane comprising peritoneum, Wharton jelly, and amnion. The umbilical cord arises from the membranous sac, and the defect may be located in the central, upper, or lower abdomen. Depending on the size and location of the defect, the hernia may contain bowel, liver, and other organs (Fig. 59-2). Omphaloceles are categorized as minor or major (giant). The definition of a giant omphalocele varies between authors and ranges from a 4 to 5 cm defect to the presence of the liver.²

Gastroschisis is characterized by a full-thickness fissure of the abdominal wall, usually to the right of midline and not involving the umbilicus. Frequently, an intact strip of skin intervenes between the umbilicus and the gastroschisis opening. This results in evisceration of intraabdominal contents without a sac or covering. Small intestine is always present, and stomach, colon, and

Fig. 59-1 An umbilical hernia is a herniation of abdominal contents into the umbilical stalk, with coverage by intact overlying skin.

Fig. 59-2 An omphalocele is a midline defect of the abdominal wall, with extrusion of intraabdominal contents that are covered by a thin membrane consisting of peritoneum, Wharton jelly, and amnion.

gonads may be involved. The exposed organs, especially the intestine, have varying severity of serositis and may be covered with a rind thought to be a result of chronic exposure to amniotic fluid (Fig. 59-3). The inflamed bowel frequently causes dysmotility and malabsorption. Gastroschisis is classified as simple or complex, based on the presence of additional bowel anomalies such as atresia, stenosis, volvulus, and perforation.³

Prune belly syndrome (Eagle-Barrett syndrome) consists of deficient musculature of the abdominal wall, cryptorchidism, and urinary tract anomalies (Fig. 59-4).

Fig. 59-3 Gastroschisis is a full-thickness fissure of the abdominal wall, with an intact strip of skin between the umbilicus and the gastroschisis opening. Abdominal contents eviscerate and have no sac or covering.

Fig. 59-4 Prune belly (Eagle-Barrett) syndrome consists of deficient abdominal wall musculature, cryptorchidism, and urinary tract anomalies.

Affected neonates can have associated pulmonary dysfunction, constipation, and renal failure. The extent of abdominal wall involvement ranges from mild hypoplasia to complete absence of the abdominal wall musculature.

EMBRYOLOGY AND PATHOGENESIS

During weeks 3 and 4 of gestation, the trilaminar disk of the developing embryo begins to fold in both the craniocaudal (longitudinal) and the transverse directions, forming a more cylindrical structure and isolating it from the embryonic membranes (Fig. 59-5).

At the completion of this folding, the cranial and caudal folds join with both lateral folds to form the ventral body wall. The central umbilical stalk is the only connection to the embryonic membranes. The resulting pleuroperitoneal canals are then divided by the septum transversum into the pleural and peritoneal cavities. In weeks 6 to 12, the rapidly elongating midgut transiently herniates into the umbilical cord as its rate of growth exceeds that of the peritoneal cavity. The

Fig. 59-5 Development of the abdominal wall. The trilaminar disk folds in the craniocaudal (longitudinal) and transverse directions. Cranial, caudal, and bilateral folds coalesce to form the ventral body wall.

midgut undergoes a 270-degree counterclockwise rotation around the axis of the superior mesenteric artery as it returns to the peritoneal cavity.

The development of an umbilical hernia is thought to result from failure of the umbilical ring to close completely. The cause of omphaloceles, however, is thought to be failure of fusion of one or more of the folds. In the most common form, failed fusion of the lateral folds results in a central abdominal defect. Involvement of the cranial fold can lead to an epigastric/thoracic defect known as the *pentalogy of Cantrell*, which includes an omphalocele, a diaphragmatic hernia, a sternal cleft, ectopia cordis, and an intracardiac defect such as a ventricular septal defect (Fig. 59-6) (see Chapter 58).

Similarly, involvement of the caudal fold can lead to a hypogastric/pelvic defect involving the urogenital system—a collection of findings known as the *OEIS complex* (omphalocele, extrophy of the bladder, imperforate anus, and spinal defects)⁴ (Fig. 59-7).

The cause of gastroschisis is not well understood, but it is thought to be a separate entity from omphaloceles. Several theories have been proposed, including thrombosis of the right omphalomesenteric vein leading to abdominal wall necrosis, a failure of physiologic herniation of the rapidly expanding midgut leading to rupture of the abdominal wall, and/or failure of mesodermal formation or penetration.

Fig. 59-6 A stillborn with an omphalocele, a sternal cleft, and ectopia cordis.

Fig. 59-7 A patient with the OEIS complex consisting of an omphalocele and extrophy of the bladder.

The cause of prune belly syndrome is not well defined but is thought to involve the development of an in utero urethra or bladder outflow obstruction, with resultant pressure effects on the abdominal wall and genitourinary tract. Aberrant mesenchymal development at 6 to 10 weeks of gestation has been suggested as an alternate mechanism.

The timing of the intrauterine event appears to be important, with earlier problems leading to more severe manifestations. The development of an omphalocele is thought to occur at about week 7 to 8 of gestation, with gastroschisis arising at about week 6 to 7. Earlier events at weeks 4 to 6 can lead to failure of fusion in all three planes. The resultant condition, known as a *body stalk defect* or *limb–body wall complex*, involves abnormalities of the head and neck, spine, extremities, and anterior body wall, with direct fusion of organs to the placenta. It carries an extremely poor prognosis.⁵

EPIDEMIOLOGY

Umbilical hernias are one of the most common congenital malformations, with a reported incidence of up to 25%.⁶ Many of these resolve without intervention, and the true incidence may be much higher. The incidence is significantly higher in black infants and in premature infants. Up to 75% of infants weighing less than 1500 g are affected.

The incidence of omphalocele is reported as 1.5 to 3 per 10,000 births and appears to be stable.⁷ Most omphaloceles arise sporadically, although rare familial cases have been reported. Omphalocele has a high incidence of associated anomalies (50% to 70%). Cardiac defects are found in 30% to 50%, whereas chromosomal abnormalities occur in up to 30% of cases. Trisomy 13, trisomy 18, and trisomy 21 are frequently observed. A variety of syndromes are associated with omphaloceles, the most common of which is Beckwith-Wiedemann syndrome.⁸

Gastroschisis is seen in 2 to 3 per 10,000 births, and unlike omphalocele, the global incidence appears to be increasing.⁸ No defined genetic causes have been identified, although the reported risk is 6% if one sibling is affected. It is associated with low maternal age, low BMI, socioeconomic status, prenatal alcohol consumption, smoking, and/or recreational drug use.⁷ In contrast to omphaloceles, associated anomalies are much less commonly seen with gastroschisis, and an abdominal wall defect is the only abnormality in more than 90% of patients⁸ (Table 59-1).

Prune belly syndrome is seen in 1 in 29,000 to 1 in 40,000 live male births. Males are predominantly affected; approximately 3% of all cases occur in females. The incidence of prune belly syndrome in twins (12.2 per 100,000 live births) is significantly greater than that seen in single

Table 59-1 Characteristics of Gastroschisis and Omphalocele		
	Gastroschisis	Omphalocele
Defect	Open	Membrane-covered
Defect size	2-5 cm	2-15 cm
Umbilical cord	Left of defect	Center of membrane
Bowel	Inflamed	Normal
Alimentation	Delayed	Normal
Associated anomalies	Uncommon	Common
Prognostic factors	Condition of bowel	Associated anomalies

births. Associated abnormalities include Potter facies, chest and abdominal wall deformities, cardiac murmurs, myocutaneous deformities, and a distended bladder.⁹

PRENATAL DIAGNOSIS AND WORKUP

A prenatal diagnosis of abdominal wall defects allows optimal management of the pregnancy, focused screening for associated anomalies, and early introduction of the parents to the surgical team. Families can be counseled about the condition, associated prognosis, and expected management. After a major abdominal wall defect is diagnosed, surgeons should consider transferring the patient to a hospital with experience and expertise in the care of these complex patients, should none be available at the existing facility.

The mainstay of prenatal diagnosis involves an ultrasound evaluation at weeks 16 to 22 of gestation (Fig. 59-8) and testing for maternal serum alpha-fetoprotein. In combination, these are 80% sensitive for the detection of abdominal wall defects.¹⁰ Maternal serum alpha-fetoprotein is more reliably elevated in gastroschisis compared with omphalocele.¹¹ A distended bladder, distended ureters, large kidneys, extremity abnormalities, cryptorchidism, and oligohydramnios detected on a fetal ultrasound examination may indicate prune belly syndrome.¹²

Fetuses with gastroschisis and omphalocele are at risk for intrauterine growth retardation, premature delivery, and in utero death. Those with an omphalocele should be evaluated for associated structural anomalies, including a diagnostic ultrasound screening for cardiac and renal defects and an amniocentesis for chromosomal abnormalities.

After the diagnosis is made, patients are followed with serial ultrasound examinations to evaluate growth, oligohydramnios, and bowel dilatation. Examinations are performed more frequently in the third trimester. A biophysical profile and fetal nonstress monitoring are indicated for physiologic evaluation.

In general, pregnancies are allowed to go to term unless changes in a fetus' condition dictate earlier delivery, although the timing of delivery is a controversial topic. Vaginal delivery is feasible for most patients with gastroschisis, whereas a cesarean section is frequently performed for patients with giant omphalocele to prevent rupture of the sac.¹³

For prune belly syndrome, in utero percutaneous vesicoamniotic shunting has been described as a means of decompressing the bladder, improving oligohydramnios, and minimizing some of the associated abnormalities.¹⁴

Fig. 59-8 A three-dimensional ultrasonographic image of the abdomen of a baby showing gastroschisis.

MANAGEMENT

With uncomplicated umbilical hernias, incarceration is rare, and small defects (less than 1 cm) generally close spontaneously by the age of 1 to 2 years. Most surgeons therefore recommend a period of initial observation, reserving surgical intervention for persistent or larger defects. The timing of surgery is controversial, although most surgeons agree that it should not be performed before a patient is 2 to 3 years of age.

The initial management of neonates with abdominal wall defects begins with the principles of airway, breathing, and circulation. They are at risk for premature delivery, and the associated bronchopulmonary dysplasia may require intubation and mechanical ventilation. Neonates with a large omphalocele may have associated pulmonary hypoplasia, which further increases the likelihood of respiratory distress. Vascular access should be obtained for fluid resuscitation and intravenous antibiotics, and the umbilical vessels are cannulated if necessary. Ultimately, all babies with gastroschisis require robust venous access for total parenteral nutrition (TPN) supplementation.¹⁵

Gastroschisis

For neonates with gastroschisis or a ruptured omphalocele, the next priority is to minimize evaporative and heat losses from the exposed viscera. Most authors recommend placing the bowel in a transparent plastic bag or wrap,¹⁶ which minimizes insensible losses, helps to control body temperature, and provides some protection while allowing continuous visual monitoring of the exposed bowel. The baby is placed right-side down with the viscera supported, to prevent kinking of the bowel's mesentery. Electrolytes and blood glucose levels are checked and corrected as required. The high fluid losses possible with exposed viscera may require much higher intravenous fluid rates for resuscitation. A nasogastric tube is placed and maintained to suction for decompression.

The bowel is examined for other pathology, including atresia, necrosis, or perforation, and the baby is examined for other associated anomalies. Tight defects of the abdominal wall may require urgent enlargement, whereas volvulus may necessitate urgent reduction. In the absence of these findings, the decision needs to be made whether to attempt immediate reduction and repair or to perform staged (silo) closure.¹⁷ A primary repair is preferred whenever feasible; however, a number of key variables can potentially prevent this option:

- The size of the defect
- The degree of abdominovisceral disproportion
- The condition of the bowel
- Extreme prematurity
- Severe pulmonary disease
- Associated conditions or anomalies

The risk of primary reduction and closure is related to the inevitable increase in intraabdominal pressure resulting from returning the viscera to the abdomen, which in turn may lead to respiratory compromise, renal insufficiency, and abdominal compartment syndrome.¹⁸ As the degree of abdominovisceral disproportion increases, these risks also rise accordingly. Similarly, in extremely premature infants or infants with severe pulmonary disease, the pulmonary status may be quite tenuous, and pulmonary function may be compromised more easily and/or more severely. In these cases, it is often more prudent to undertake staged closure. Several studies have compared the outcomes of primary closure versus silo closure for gastroschisis, looking at overall complication rates, time on the ventilator, time to full feeds, and length of hospital stay. Although the results of these studies can be difficult to interpret because of inherent selection bias, with judicious patient selection the outcomes can be equivalent.^{19,20}

Primary Reduction and Repair

Primary reduction and repair is generally performed with the patient under a general anesthesia with a neuromuscular blockade. A urinary catheter is placed not only to measure urine output but also to periodically measure bladder pressure intraoperatively and postoperatively. Bladder pressure and peak airway pressures are proxies for determining intraabdominal pressure, and significant elevation of this value after reduction of the viscera may indicate that primary fascial closure is not advisable at the first stage.

Bladder pressures greater than 10 mm Hg are considered elevated in children,²¹ and some authors advocate a hard cutoff value of 20 mm Hg in deciding whether to proceed with primary repair. Although parameters have been documented for bladder pressure indicating intraabdominal hypertension and acute abdominal compartment syndrome, there are no absolute values for peak airway pressures that vary significantly between patients, dependent on age and preexisting pulmonary comorbidity. Therefore relative changes in peak airway pressures are used as a proxy for increased intraabdominal pressure and the ability to extubate the patient after surgery. Trending the changes in bladder pressure and airway pressures should be continued into the immediate postoperative period.²²

Near-infrared spectrometry (NIRS) is an additional noninvasive methodology that reliably reflects visceral tissue oxygenation and perfusion in neonates weighing less than 10 kg. Although frequently used on larger babies, its reliability and usefulness in larger babies are controversial.²³

The bowel should be carefully examined before reduction and areas of atresia, stenosis, and vascular compromise noted. Vascular compromise can result from a tight fascial defect, in which case urgent enlargement of the defect is indicated.²⁴ Attempted separation of inflamed, matted loops of bowel before reduction is not advisable, because it frequently results in enterotomy. In the absence of intestinal compromise, the bowel mass is reduced through the defect. The bladder, airway pressures, and NIRS values (if available) should be noted before and after attempted reduction; if pressures are not excessively elevated and NIRS measurements did not decrease, fascial closure can be performed. The skin and subcutaneous fat are elevated circumferentially from the fascia, exposing the fascial defect, which is often quite small. Primary suture repair of the myofascial defect can then be carried out, followed by layered closure of the overlying tissues.

If intestinal atresia is identified, it may be possible to resect the affected segment and perform a primary anastomosis at the same operation. This is dependent on the overall condition of the bowel and the location and extent of the atretic segment. Other options include the formation of an end ostomy for distal atresia or simple reduction of the unrepaired bowel with repair of the abdominal wall, deferring repair of the intestine to a second stage.²⁵ Similarly, areas of bowel necrosis may be treated with resection and primary anastomosis under ideal conditions or may require ostomy formation or tube decompression.²⁶

After closure, the abdomen should remain soft; parameters reflecting intraabdominal pressure and visceral perfusion mentioned previously should be stable, and acidosis should not develop. If any one of these criteria is not met, then primary repair is abandoned and a staged approach chosen instead.²⁷ Some authors have advocated that, to minimize physiologic embarrassment, viscera may be reduced at the bedside with mild sedation and spontaneous ventilation,²⁸ whereas others have recommended a staged closure with silo placement in all cases.²⁹

Staged Silo Repair

Schuster¹⁷ first described the creation of a silo, consisting of Teflon sheets sewn together to cover the exposed bowel and sutured to the abdominal wall under moderate tension. This was covered with mobilized skin flaps, which were periodically reopened to facilitate serial tightening and removal of the Teflon. Allen and Wrenn²⁷ subsequently modified the technique to use Silastic sheets instead of Teflon, leaving the construct exposed to facilitate monitoring of the viscera and

Fig. 59-9 A prefabricated Silastic silo is suspended above the patient to allow gradual reduction of the viscera into the abdominal cavity.

serial tightening. This became the standard technique for staged repair until the introduction of a prefabricated Silastic silo (Dow Corning) coupled to a spring-loaded ring (Bentec) in the 1990s.²⁹ With this device, the spring-loaded ring will hold the silo in place as long as the fascial ring is intact. It can be placed at the bedside without anesthesia and is suspended overhead (Fig. 59-9).

The now-protected bowel becomes less swollen and edematous as the neonate physiologically diureses over the next several days. This, coupled with gravity, allows the bowel to gradually reduce back into the peritoneal cavity. The silo can be serially tightened by placing a clamp across the top to hasten the reduction. This process may take 1 to 14 days, after which the skin, fascia, or both can be closed. Silo placement remains the standard of care for gastroschisis patients in whom primary closure is not feasible. Some authors have reported on a “plastic” sutureless closure technique, in which the viscera are reduced as before, and the umbilical cord is trimmed and laid over the gastroschisis defect and covered with an adhesive dressing.³⁰ Proponents of the technique cite improved scarring and umbilical positioning; however, resultant ventral hernia rates are high (up to 84%), and this has not been universally accepted.

Omphalocele

Evaporative and heat losses are less with omphalocele compared with gastroschisis, because of the presence of the sac covering the viscera. Surgery often is less urgent, and managing associated anomalies may take precedence over definitive correction of the omphalocele. Initial management, as for gastroschisis, involves airway stabilization and temporary coverage of the defect. The omphalocele sac can be covered with moist gauze and a plastic wrap, and the neonate should undergo a complete evaluation for associated anomalies, including undiagnosed genetic syndromes. An echocardiogram and renal ultrasound are carried out.³¹

After this initial management, attention is turned to the omphalocele. As for gastroschisis, the decision to attempt early reduction and fascial closure is guided by the size of the defect and the degree of abdominovisceral disproportion. The overall condition of the infant and comorbidities, particularly pulmonary hypoplasia, are also important factors.

For small omphaloceles smaller than 2 to 4 cm, early reduction with primary fascial closure is the benchmark and has been shown to result in less sepsis, fewer operations, and lower mortality.²⁸ The amniotic sac is removed and the bowel examined for associated atresia and malrotation. After reduction, the operation proceeds much the same as for gastroschisis, with elevation of skin flaps, freeing of the fascial edges, and primary myofascial suture repair. Intraabdominal and airway pressures guide the surgeon both intraoperatively and postoperatively.²²

For large omphaloceles and cases in which the intraabdominal pressures preclude early reduction, staged closure may be undertaken. A Silastic silo or Teflon pouch can be used, as for gastroschisis. However, the umbilical ring tends to be less robust in an omphalocele; therefore the spring-loaded ring is ineffectual, and the device is sutured directly to the fascia. The sac is left intact throughout this process as a barrier to infection and subsequent adhesions, and serial tightening can be performed. After the viscera are returned to the abdomen, the infant is taken to the operating room for removal of the device and repair of the fascial defect. Mesh repair of the fascia has been described³²; however, we prefer not to use this whenever possible. Intraoperative tissue expansion, as originally described by Sasaki,³³ can be used to obtain moderate gains in abdominal domain, facilitating closure of larger defects.

The umbilical cord is invariably ligated during an omphalocele repair, leaving no umbilicus. A pseudoumbilicus may be created with a purse-string or local skin flap technique, either at this operation or a later stage.

For giant omphalocele defects and for infants too unstable to undergo extensive surgery, a delayed repair is performed. In this technique, the omphalocele defect is covered with skin, but no attempt is made to reduce the abdominal contents or close the fascia. Gross³⁴ originally described the mobilization of bipediced flank skin flaps to cover the omphalocele sac, with skin grafting to the donor sites. At the time, this represented a major advance in the surgical management of these patients. However, in common with all delayed repairs, it did not address the potentially massive ventral hernia that invariably resulted.

Delayed repair initially can be managed nonoperatively, and in many centers this has become the standard for treating giant omphaloceles. The omphalocele sac is treated with a topical agent that promotes eschar formation and is allowed to reepithelialize from the edges, a process that may take up to 10 weeks. Initial reports used mercurochrome, alcohol, or silver nitrate; each was effective but associated with potential toxicity.³⁵ Silver sulfadiazine (Silvadene) has emerged as an excellent alternative with less potential toxicity.³⁶ Dressings are performed twice daily until epithelialization is complete and may potentially be completed on an outpatient basis in selected patients.³⁷ Gentle compressive wraps can be placed as an adjunct during and after reepithelialization to support the abdominal mass and to encourage gradual return of the abdominal contents into the abdomen in preparation for a definitive hernia repair, usually 6 to 12 months later.³⁸ Alternatively, skin coverage may be expedited using skin grafts directly on the omphalocele sac, preventing the need for a prolonged period of dressing changes.

The management of omphaloceles requires a team approach, and multiple surgical specialties may be involved. In particular, low omphaloceles associated with cloacal extrophy or OEIS complex will require a pediatric surgeon, plastic surgeon, urologic surgeon, and an orthopedic surgeon to work closely together. Similarly, high omphaloceles associated with sternal, thoracic, or cardiac anomalies will require the input of a pediatric and a cardiothoracic surgeon. A complete discussion of the management of these complex patients is presented in Chapter 58.

Prune Belly Syndrome

Similarly, patients diagnosed prenatally with, and those who are suspected of having, prune belly syndrome should be transferred to a hospital with pediatric specialty services, including an experienced obstetric and neonatal team, pediatric urologists, and reconstructive surgeons. The extent of abdominal wall weakness in prune belly syndrome ranges from mild hypoplasia to complete absence of the musculature. Milder manifestations of this condition may benefit from fascial plication, whereas moderate to severe deficiencies require more extensive surgical intervention. A variety of approaches have been described, most of which involve excision of redundant fascia and placement of mesh. Lesavoy et al³⁹ reported on a series of 20 patients with moderate to severe prune belly syndrome, who underwent an overlapping “double-breasted” fascial repair with concurrent urologic repair. The authors reported good results, with only three patients having a reoperation for right-sided fascial laxity within the long follow-up period (mean 20 years).

In the most severe forms of prune belly syndrome, the abdominal musculature is completely absent. The outcomes of abdominal reconstruction in this patient group are uniformly poor, and surgeons should consider an abdominal wall transplant for patients who are candidates for a kidney transplantation or a posterior rectus sheath–liver vascular composite allotransplantation if a multivisceral transplant, including the liver, is indicated.^{40,41}

POSTOPERATIVE CARE

The initial postoperative management of infants with abdominal wall defects varies by condition, severity, and the presence of associated anomalies or comorbidities. In general, mechanical ventilation is continued for a few days postoperatively. This is particularly true after closure of larger omphaloceles, where it is beneficial in the short-term to maintain neuromuscular blockade (paralysis) and sedation during the early postoperative period. During this time, nasogastric tube decompression is continued. Continued monitoring of bladder and airway pressures is often warranted, and judicious fluid administration may help to limit edema formation.

Once bowel edema has subsided and intraabdominal pressures have decreased, then paralysis and sedation can be safely lifted and the patient weaned from the ventilator as tolerated according to comorbidities, particularly pulmonary hypoplasia. The same holds true after repair of gastroschisis; however, the loss of abdominal domain is usually less than with giant omphaloceles; therefore resultant intraabdominal pressures may be less extreme.

Infants with gastroschisis uniformly require central venous access and total parental nutrition, because the exposed intestine invariably demonstrates dysmotility and absorptive dysfunction. Enteral feeding is deferred until 2 to 3 weeks after repair in many cases. The presence of bowel atresia or other types of complex gastroschisis may delay this even further.³

Omphalocele patients may require TPN in the short term, depending on the extent of the omphalocele and associated morbidity. However, the intestinal dysmotility and absorption abnormalities seen with gastroschisis are generally not present in omphalocele patients; therefore the need for TPN and the duration of treatment are generally less.

OUTCOMES

The long-term outcomes for infants born with congenital abdominal wall defects have improved dramatically since the 1960s, in large part because of the introduction of TPN,¹⁵ advances in ICU care, and the recognition that staged repair may be necessary in larger defects.¹⁷ In the absence of associated anomalies, the prognosis after an abdominal wall repair is generally excellent.

As discussed previously, infants with gastroschisis can have delayed bowel function and prolonged TPN requirements, and a period of catch-up growth is the rule after successful feeding has begun. With prolonged TPN comes the possibility of associated complications, including line sepsis and TPN-associated cholestasis. Survival from gastroschisis is greater than 90% and generally related to the degree of intestinal loss.⁴² The length of hospital stay is also related to bowel dysfunction, with tolerance of enteral feeds delayed longer than 2 months in up to 25%.⁴³ In addition, necrotizing enterocolitis can develop after repair of gastroschisis, contributing to delayed intestinal function and subsequent malabsorption or short-gut syndrome.⁴⁴ In the long term, most patients are able to tolerate full enteral feeds and catch up in growth satisfactorily.⁴⁵ However, prolonged TPN in infants may be further complicated by oral aversion to food, requiring long-term behavioral and swallowing therapy while nutrition is maintained through a nasogastric or gastrostomy tube. It has been reported that the method of closure does not affect survival, length of stay, or duration of TPN, whereas duration of mechanical ventilation appears to be slightly shorter with use of a silo versus primary closure.¹⁹

The overall survival for neonates with an omphalocele is significantly lower, at 60%, and is more highly dependent on the presence of associated anomalies. Survivors tend to have higher rates of chronic morbidity, including pulmonary hypoplasia, gastroesophageal reflux, and failure to thrive.⁴⁶

Despite these issues, the quality of life in the survivors of both gastroschisis and omphalocele have been reported as good to very good and not significantly different from that of the general population.⁴⁷ As an example, a significant proportion of these patients report the appearance of the umbilicus, or lack thereof, as one of their most prominent long-term concerns.^{46,48}

The mortality of patients with prune belly syndrome depends on the degree of pulmonary hypoplasia and the development of renal failure. In the past, approximately half of the patients with prune belly syndrome died in the neonatal period. The advent of in utero vesicoamniotic shunts has significantly improved early survival.¹⁴ Although many of these patients had improved renal and bladder function, approximately a third of these infants ultimately required dialysis and/or renal transplantation.

ALTERNATIVE TREATMENTS AND MANAGEMENT OF SECONDARY HERNIA DEFECTS

The treatments presented previously are the standard of care for patients with congenital abdominal wall defects from gastroschisis or omphalocele. However, several additional strategies have been reported with varying degrees of success.

The use of negative pressure wound therapy (wound vacuum-assisted closure [VAC]) has been described as an alternative to silo treatment, facilitating gradual reduction of the extracoelomic contents in small case series.⁴⁹ The reported benefits include continual pressure on the extracoelomic mass, preoperative reduction of the viscera, and splinting of the omphalocele contents. The authors also described its later use over an intact skin graft, reportedly increasing abdominal domain in preparation for definitive ventral hernia repair in a patient 8 months of age. Although these results, and those of other small series, are promising, negative pressure wound therapy has not been extensively studied in these patients and has not been universally accepted.

The inevitable loss of intraabdominal domain seen with giant omphaloceles has also been addressed through the use of tissue expanders. These devices potentially allow a rapid increase in abdominal domain, creating space for reduction of the abdominal contents without a dangerous increase in intraabdominal pressure. Some have described placement of the expanders in the subcutaneous plane, between the internal oblique and the transversus abdominis muscles, and intraperitoneally. Complications, including infection, deflation, extrusion, and displacement or malposition, have limited tissue expanders' efficacy and routine use.^{50,51}

Component separation has also been described for managing patients with omphaloceles or gastroschisis, with promising initial results. In a recent case series, Levy et al⁵² reported on the use of component separation in nine children with a median age of 1.1 years at operation. In four patients, the technique was used for recurrent ventral hernias. Component separation was used as a first-line treatment to primarily close the fascia in three neonates, with no evidence of recurrence within a follow-up of 16 months. The authors used acellular dermal matrix (ADM) reinforcement in eight of nine patients. Although component separation successfully closes these large ventral abdominal wall defects, the long-term effects of disuse atrophy of the external oblique muscles that frequently occurs with component separation have not been evaluated.

The use of ADM and other bioprosthetic materials such as small intestinal submucosa (Surgisis; Cook Surgical) is growing in popularity in many areas, including abdominal wall reconstruction. Purported advantages of these materials over prosthetic mesh include tissue incorporation and revascularization, the ability to grow with the child, and the ability to use it in a contaminated field.⁵³ In a report on three patients with complex gastroschisis, small intestinal submucosal bioprosthetic Surgisis was used to patch the fascial defect and was covered with a negative pressure dressing until granulation and skin graft or reepithelialization.⁵⁴ Similarly, Beres et al⁵⁵ described the use of Surgisis for fascial repair in nine patients with omphaloceles and two patients with gastroschisis. They reported a 38% recurrent hernia rate. In an earlier report, Kapfer and Keshen⁵⁶ reported on the use of Alloderm (LifeCell) human ADM bioprosthetic for early fascial reconstruction in three patients with a giant omphalocele. The Alloderm material was left partially exposed in two patients and dressed with serial cadaveric allograft dressings. The authors reported no infections and no fascial dehiscences.⁵⁶ Although these materials may work well to prevent dehiscence in the short term, when used to bridge a gap, they will invariably cause a bulge or result in recurrent herniation in the long term.

Similarly, an ADM can be used during the intermediate steps of planned, multistage repair in the secondary management of hernia defects resulting from delayed closure of omphalocele defects, as described in the following case.

In patients undergoing solid organ transplant, an abdominal wall transplant represents another potential method of addressing loss of abdominal domain. Levy et al⁵² reported on a series of patients undergoing both a small bowel and abdominal wall transplant, one of whom was a child with gastroschisis. Similarly, Ravindra et al⁴⁰ published their experience of a concurrent transplant of small bowel, pancreas, liver, and posterior rectus sheath in a patient with gastroschisis, short bowel syndrome, loss of abdominal domain, and TPN-induced cholestasis. They performed a multivisceral transplant using the posterior rectus sheath attached to the liver through the falciform ligament. The posterior rectus sheath component of this vascular composite allograft was used to repair the abdominal wall fascial defect.

CASE EXAMPLE

This 23-month-old boy was born with a giant omphalocele and associated pulmonary hypoplasia. Because of pulmonary hypertension and other complicating factors, his omphalocele defect was treated in a delayed fashion with Silvadene but was complicated by bowel perforation. He was managed with placement of a Silastic silo and Vicryl mesh (Fig. 59-10, *A*), and skin grafting was performed several weeks later. He was transferred for further management, presenting with a large ventral hernia under a healed skin graft and severe loss of domain (Fig. 59-10, *B* through *D*).

A staged repair was planned, which included insertion of intraabdominal tissue expanders to increase abdominal cavity capacity and placement of subcutaneous tissue expanders (Fig. 59-10, *E*) to provide healthier skin closure over a temporary ADM that was planned to be inserted at a second stage.

Fig. 59-10 A, A silo was sutured in place. B, He had a giant omphalocele at 2 years of age, with healed skin graft coverage. C, Lateral CT showed the small size of the abdominal cavity versus the large size of the omphalocele. The AP diameter of the abdominal cavity was about 1.5 cm, and the AP diameter of the omphalocele was 9.3 cm. The transverse diameter of the abdomen was 11.8 cm, as opposed to the transverse measurement of the omphalocele of 13 cm. D, Coronal CT demonstrated the discrepancy of the abdominal capacity versus the size of omphalocele. E, The patient is shown 1 month after expander placement.

Continued

Fig. 59-10, cont'd F, Viscera were partially reduced into the expanded abdominal cavity and covered with an ADM. G, Residual skin graft and the expanded skin were approximated over the ADM. H, Fascial edges are secured with Lahey clamps. I, With intermittent stretch-relaxation, the edges were brought toward midline. J, Fascia to fascia closure.

Fig. 59-10, cont'd **K**, Six months later, the patient was prepared for a gastrostomy tube placement. **L**, He is shown 1 month after placement of the gastrostomy tube and 18 months after the initial insertion of tissue expanders.

The plan was complicated by extrusion of one of the subcutaneous expanders, necessitating early removal and deflation of one of the intraabdominal expanders, because it slipped into the extraabdominal component of the omphalocele. Despite this, the second stage proceeded with partial reduction of his viscera and placement of a temporary porcine ADM (Fig. 59-10, *F*).

Because of the loss of one of the expanders, only a part of the skin graft could be excised. Residual skin graft and the expanded skin were approximated over the ADM (Fig. 59-10, *G*), and the bladder and airway pressures remained stable throughout. With partial reduction of the liver, his pulmonary hypertension improved significantly. One week later, the patient underwent plication of the porcine ADM Strattice mesh (LifeCell) and further excision of the skin graft. A small area of wound breakdown resulted in exposure of the ADM, which was removed 3 weeks later and replaced with a smaller ADM underlay patch. On completion of this repair, increased bladder pressure and oliguria were noted intraoperatively, necessitating release of the reconstruction and the use of a larger ADM patch. The skin was reapproximated over this.

This reconstruction was again complicated by minor wound breakdown, and 3 months later he developed an infection of the abdominal wall. The ADM was removed. The abdominal wall was expanded intraoperatively using a stress-strain-relaxation technique, and primary fascial approximation was achieved (Fig. 59-10, *H* through *J*).

Intraoperative monitoring included bladder pressures and the use of a NIRS device placed on the skin over one kidney. He tolerated the procedure very well, and was extubated on the first postoperative day.

Seven months later, at 38 months of age, the patient underwent a repeat laparotomy with gastrostomy tube placement for management of persistent feed aversion (Fig. 59-10, *K*). He had no evidence of recurrent hernia. On attempted reclosure of the abdomen, the fascia felt thin; therefore a unilateral myofascial advancement flap was performed to reinforce the central closure.

Six months postoperatively, the patient is progressing well with no evidence of herniation, and his oral intake and respiratory status are steadily improving (Fig. 59-10, *L*).

CONCLUSION

In the broad spectrum of congenital abdominal wall defects, the two most common are omphaloceles and gastroschisis. The outcomes of these conditions have dramatically improved over the last 50 years because of improved technique selection, ICU care, and TPN. For patients with gastroschisis, intestinal function is generally poorer, but overall survival is greater than 90%. For those with omphaloceles, gastrointestinal function is less impaired, but overall morbidity and mortality are much higher because of the high incidence of associated anomalies. Despite associated morbidities, quality of life can be very good in survivors and will continue to improve as surgical management strategies continue to evolve.

KEY POINTS

- Congenital abdominal wall defects comprise omphaloceles, gastroschisis, and prune belly syndrome.
- Serial antenatal ultrasounds are critical after the diagnosis of an abdominal wall defect.
- Percutaneous in utero vesicoamniotic shunting significantly improves early survival and minimizes associated deformities in patients with prune belly syndrome.
- Early fluid and heat losses can be significant with gastroschisis or ruptured omphalocele, and coverage of the exposed bowel is a surgical emergency.
- Evaporative losses are much less with omphalocele than with gastroschisis.
- The incidence of associated anomalies is much higher with omphalocele, and these should be actively sought.
- The ultimate goal of treatment is adequate coverage of the viscera.
- The size of a defect, the degree of abdominovisceral disproportion, and associated morbidities dictate the method of treatment.
- Staged or delayed repair may be necessary in selected cases.
- The physiologic impact of an omphalocele is related to its size and the presence of associated anomalies.
- In gastroschisis, the bowel does not function properly, but the child rarely has other serious issues.
- Alternative treatment methods such as tissue expansion, negative pressure wound therapy, and the use of bioprosthetic mesh can help to optimize outcomes.

Pediatric Breast Anomalies

Ann R. Schwentker • A. Michael Sadove • John A. van Aalst

Pediatric breast anomalies span a wide range of conditions. Some, such as polythelia, are relatively common and present as isolated abnormalities, whereas others, such as amastia, are rare and may present with a constellation of congenital issues. Treatment of breast abnormalities involves decisions about the type and timing of treatment and consideration of patients' immediate and future aesthetic requirements.

Pediatric breast anomalies may be classified as hypoplastic, hyperplastic, or deformational.^{1,2} Hypoplastic conditions are characterized by breast tissue paucity and include hypoplasia, tuberos breast, Poland syndrome, athelia, and amastia. These conditions require augmentation procedures. Hyperplastic anomalies are characterized by excess breast tissue and include polythelia, polymastia, gynecomastia, juvenile hypertrophy, and giant fibroadenomas. These conditions require treatment with excision techniques. Deformational anomalies include alterations in breast growth resulting from surgical, traumatic, and burn scars, or chest wall asymmetry resulting from scoliosis or pectus excavatum. These deformities may require a combination of augmentation and excision procedures.

NORMAL BREAST DEVELOPMENT

The breast develops during the sixth week of gestation from an anlage of ectodermal cells along the milk lines, or primitive mammary ridges, which extend from the axilla to the groin. By the tenth week of gestation, the upper and lower parts of these ridges atrophy; at the level of the fourth interspace, the middle or pectoral ridges persist and later develop into breast tissue. The areola develops in the fifth month of gestation, and the nipple appears shortly after birth.³

After birth, circulating maternal estrogens may cause breast tissue enlargement. As maternal estrogens are metabolized, the breast tissue involutes, remaining quiescent throughout childhood. During childhood, the breast consists of epithelial-lined ducts with surrounding connective tissue. At the onset of puberty, hormonal influences in females result in breast tissue growth; that is, estrogens cause ductal and stromal tissue growth, and progesterone causes alveolar budding and lobular growth.⁴ Thelarche, the onset of breast growth, occurs at an average age of 11 years (normal range 8 to 15 years of age) and usually precedes menarche by at least a year. Tanner⁵ described breast development as proceeding through stages I through V, with breast maturity occurring in stage V. Nipple size differentiation occurs between Tanner stages IV and V.⁶ Breast growth may be variable, but is generally complete by 16 to 18 years of age.

CLASSIFICATION OF BREAST ABNORMALITIES

Hypoplastic Breast Abnormalities

Breast hypoplasia (with an intact nipple-areola complex) can be unilateral or bilateral.

Tuberous breast deformities are characterized by breast hypoplasia (Fig. 60-1), and include the following⁷:

- A deficiency in the base diameter
- Breast tissue herniation into the areola
- A deficient skin envelope
- Elevation of the inframammary fold

Several classification systems have been developed to describe tuberous breasts.⁷⁻⁹ Meara et al⁹ proposed a three-tier system in which type I tuberous breasts have medial quadrant hypoplasia, type II have lower medial and lateral quadrant hypoplasia, and type III have severe breast

Fig. 60-1 This patient has a right type III tuberous breast deformity.

Table 60-1 Tuberous Breast Grading System

Type	Breast Base	Inframammary Fold	Skin Envelope	Breast Volume	Ptois
I	Minor constriction	Minor elevation medially	Sufficient	Minimally deficient	None
II	Moderate constriction	Elevation medially with minor elevation laterally	Insufficient inferiorly	Mild to moderate deficiency	Minimal to moderate
III	Severe constriction	Elevation of the entire fold	Insufficient circumferentially	Severe deficiency	Severe

**Fig. 60-2** This young male has left Poland syndrome. His pectoralis muscle is absent.

constriction^{9,10} (Table 60-1). As the grade of tuberosty increases, the deformity involves a progressive elevation of the inframammary fold, an increasing paucity of skin, a decreasing breast volume, and increasing ptosis.

Poland syndrome is a chest wall deformity affecting 1 in 20,000 to 1 in 30,000 live births that usually results in a more significant breast hypoplasia than tuberous breast (Fig. 60-2). Poland's initial description of the deformity included pathognomonic absence of the sternal head of the pectoralis major and brachysyndactyly of the ipsilateral hand, which can be variable.¹¹ Other possible associated findings include absent ribs, chest wall depression, athelia or amastia, absent axillary hair, and deficient subcutaneous fat. The anomaly is usually unilateral and sporadic, but rarely bilateral or familial.^{10,12,13} A similar condition, anterior thoracic hypoplasia, consists of a unilateral sunken chest wall with hypoplasia of the breast and a superiorly displaced nipple-areola complex. These individuals have a normal sternal position and a normal pectoralis muscle¹⁴ (see Chapter 58).

Athelia (absence of the nipple), amazia (absence of the mammary gland), and amastia (absence of the nipple and gland) are rare congenital hypoplastic anomalies^{2,15,16} (Fig. 60-3). Three groups of amastia patients have been described: (1) those with bilateral absence of the breast secondary to congenital ectodermal defects, (2) those with unilateral absence of the breast (a variant of

Fig. 60-3 This male infant has athelia.

Poland syndrome), and (3) those with bilateral absence of the breast.¹⁶ Amastia associated with congenital ectodermal defects affects males and females and is characterized by abnormalities of the skin and appendages, including the teeth and nails. Bilateral absence of the breast may occur as an isolated abnormality, or it may be associated with clefts of the palate and upper extremity anomalies. The defect can be sporadic or familial.¹⁶

Hyperplastic Breast Anomalies

Hyperplastic breast anomalies are characterized by excessive breast tissue. The most common form of hyperplasia seen by pediatric plastic surgeons is polythelia, which is the presence of supernumerary nipples or entire nipple-areola complexes. This anomaly results from failure of the superior or inferior primitive mammary lines to fully atrophy. Polythelia occurs in males and females and has a reported incidence as high as 5.6%.^{17,18} It generally occurs sporadically and in rare instances may be associated with nephrourologic anomalies;¹⁹ familial cases have also been reported. Polythelia can occur at any point along the embryonic milk line from the axilla to the groin² (Fig. 60-4).

Polymastia, the presence of more than two breasts, is a rarer condition than polythelia and may occur anywhere along the embryonic milk line.²⁰ It is usually sporadic, but familial cases have been reported; latent cases may become noticeable during puberty, pregnancy, or lactation. Polymastia can occur as an isolated finding or may present with congenital renal anomalies^{2,21} (Fig. 60-5).

Gynecomastia, enlargement of the breast in males, affects up to 65% of males 14 to 15 years of age. It is initially characterized by fibroblastic stromal and ductal proliferation producing a palpable infraareolar breast bud, and it generally resolves spontaneously without surgical intervention.²² Gynecomastia persists in 10% of affected boys at 17 years of age.²³ If the condition persists beyond a year, fibrosis and hyalinization occur with regression of epithelial proliferation, increasing the likelihood that surgical intervention may be required. Simon et al²⁴ proposed a three-grade classification system for gynecomastia in which grade I is characterized by slight breast enlargement without skin redundancy and for which reassurance that the condition should resolve without intervention is appropriate. Grade IIA is characterized by moderate breast enlargement without skin redundancy; grade IIB involves moderate breast enlargement with marked skin redundancy; and grade III has marked breast

Fig. 60-4 This patient with left polythelia has an accessory nipple just below the inframammary fold.

Fig. 60-5 A, Left polymastia. B, An intraoperative view of the resected tissue.

Table 60-2 Gynecomastia Grading System

Grade	Breast Size	Skin Amount
I	Slight breast enlargement	No redundancy
IIA	Moderate breast enlargement	No redundancy
IIB	Moderate breast enlargement	Marked redundancy
III	Marked breast enlargement	Marked redundancy

enlargement and skin redundancy²⁴ (Table 60-2). An endocrine evaluation to rule out a reversible cause of gynecomastia, especially testicular and adrenal tumors, is recommended.

Pediatric breast hypertrophy, or juvenile hypertrophy, has an unknown cause. It is not associated with endocrine abnormalities, and patients otherwise exhibit normal growth. Prepubertal hypertrophy is very rare and generally bilateral, whereas virginal hypertrophy, which develops after puberty, may be either unilateral or bilateral. Patients can have asymmetry from unilateral hyperplasia, bilateral symmetrical hyperplasia, or a combination of hypertrophy and hypoplasia.²⁵

Fig. 60-6 A, This patient had a giant fibroadenoma. B, The excised lesion. C, The postoperative result.

Giant fibroadenoma, a rare form of hypertrophy, is a benign, discrete lesion that presents during puberty as a unilateral, rapidly growing breast mass (Fig. 60-6). These lesions are the result of breast tissue hypersensitivity to normal levels of gonadal hormones. The diagnosis is confirmed with a breast tissue biopsy.

Deformational Breast Anomalies

The most common deformational breast anomalies are growth disturbances caused by scarring, which may be iatrogenic or secondary to trauma and burns. A common iatrogenic injury in females develops from a right anterolateral thoracotomy for cardiac surgery (Fig. 60-7); surgery performed before puberty may result in a mature breast volume difference in 55% of patients and deficiencies in the lower pole of the right breast in 61% of patients, compared with 0% of patients undergoing a median sternotomy for a similar procedure.²⁶ This has led many cardiac surgeons to abandon thoracotomy incisions in female patients.

Severe burns can cause restrictive scarring that affects breast development. Deformities may include loss of the inframammary fold, synmastia (medial confluence of the breasts), upward or downward displacement of the breast mound, and loss of the nipple-areola complex (Fig. 60-8).

Fig. 60-7 This adolescent girl developed a right breast deformity after an anterolateral thoracotomy.

Fig. 60-8 This patient has a constricted breast deformity resulting from burn scars.

Synmastia is rarely congenital but most often the result of prior surgery or trauma. Spence et al²⁷ first described the condition in 1983. It is characterized by the absence or effacement of the presternal cleft between the breasts.

Deformities of the thoracic cage may result in apparent breast asymmetry or exacerbate actual asymmetry. Patients with pectus excavatum, pectus carinatum, and scoliosis initially can present with breast asymmetry and may require further studies, including CT, to determine whether the spine and/or chest wall deformities also require treatment.

Treatment Strategies

Timing

The timing of reconstruction is important in maturing females. It is often advisable to delay breast surgery until breast development is complete, because breast growth may be variable and asymmetrical, even in healthy individuals.²⁸ Breast growth is presumed to be complete when no change in bra size has occurred for at least a year. Asymmetry of up to a full cup size is considered normal, but more severe asymmetries are pathologic and can result in back, neck, and shoulder pain that improves with breast reduction.²⁹ In patients with asymmetry, operating on the normal breast should be delayed until breast growth is complete. Operating on a growing breast may result in unnecessary surgical revision after growth is completed; however, earlier operation is

Fig. 60-9 A and B, This patient had a bilateral tuberous breast deformity. C and D, She is shown postoperatively after release of breast tissue herniated into the nipple-areola complex and a bilateral augmentation mammoplasty.

indicated and may be beneficial in several situations, such as gross asymmetry of the breast from giant fibroadenomas.

Correct placement of the inframammary fold and nipple-areola complex, balanced and symmetrical breast mounds, and maintenance of normal presternal breast separation are critical for effective reconstruction of any breast deformity. The placement of scars should also be carefully considered to provide the best aesthetic result.

Implants

Breast reconstruction or augmentation is performed with implants, pedicled or free autologous tissue transfer, fat transfer alone, or in combination with other techniques.

Implant reconstruction can be performed as the sole procedure if the volume deficit is small. Stretch marks may result if an overly large implant augmentation is attempted. In patients with skin deficiency, a preliminary procedure to reposition the inframammary fold and insert a tissue expander may be performed to allow expansion of the skin envelope before definitive augmentation.³⁰ When the breast base is severely constricted, as in tuberous breast anomalies, the breast tissue must be incised in a radial fashion to allow the breast envelope to expand to fit over the implant² (Fig. 60-9).

When saline implants are used for reconstruction in severely hypoplastic breasts, especially if submuscular placement is not possible, implant palpability and rippling may result; silicone implants, which are less likely to cause these problems, can give more aesthetically pleasing results. The likelihood for revision surgery, rupture, capsular contraction, and implant interference with mammographic imaging is high. Reconstruction in patients with amastia should be performed cautiously, because aberrant blood supply to the skin can cause unpredictable healing.³¹

Fig. 60-10 A and B, This patient had Poland syndrome with left breast hypoplasia and absence of the pectoralis major muscle. C and D, After reconstruction with a latissimus dorsi flap and implant placement, she has improved breast symmetry and subclavicular soft tissue contour.

In patients with Poland syndrome, anterior thoracic hypoplasia, and pectus deformities, chest wall deformities can be reconstructed with custom solid silicone implants. This treatment may be most appropriate in male patients with Poland syndrome in whom the use of the latissimus dorsi muscle would be noticeable. Some authors have been critical of these implants, because they are visible under the skin envelope; however, this problem can be prevented by covering the implant with a latissimus dorsi flap³² or with fat grafting.

Tissue Flaps

Some authors recommend the use of inferiorly based flaps to reconstruct breast contour in patients with inferior pole deficiency.³³ This technique results in a smaller breast than can be achieved with implants and is appropriate for milder cases of tuberous breast deformities. Latissimus and rectus abdominis myocutaneous flaps can also be pedicled to reconstruct the absent tissue. A latissimus dorsi flap combined with a breast implant can be a very effective means of reconstructing a severe Poland deformity (Fig. 60-10). Some authors have advocated using endoscopy or even a surgical robot to assist in the harvest and placement of the latissimus dorsi flap^{20,34}; however, we have found that a relatively small incision suffices for this procedure, obviating the need for this technology. Once harvested, the latissimus dorsi flap must be inset carefully along the infraclavicular margin to prevent recurrence of the infraclavicular hollow. We prefer the latissimus dorsi flap because of the high reoperation rates among patients undergoing synthetic chest wall reconstruction without myocutaneous flap coverage.^{1,20}

Free tissue transfer has been useful in patients requiring a large amount of tissue for reconstruction and includes the use of free transverse rectus myocutaneous flaps, deep inferior epigastric perforator flaps, and less commonly used flaps such as a transverse upper gracilis and a

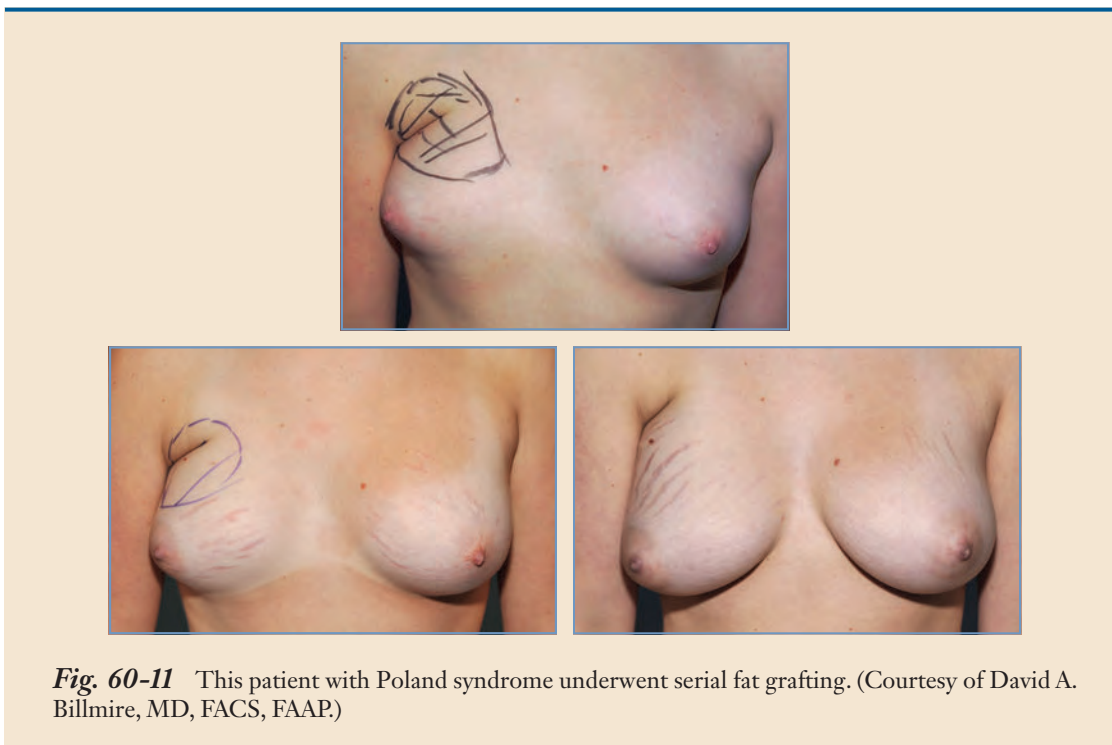

Fig. 60-11 This patient with Poland syndrome underwent serial fat grafting. (Courtesy of David A. Billmire, MD, FACS, FAAP.)

Rubens.³⁵ These are complicated procedures with significant risks; therefore they should be delayed until breast development is complete to prevent unnecessary revisions. Tissue transfer prevents the problem of anomalous blood supply to the chest wall skin and may be especially useful for severe scarring of the breast skin, as in burn scar reconstruction.

Fat Grafting

The technique of micrografting autologous fat is relatively new but has been used in many different applications in plastic surgery over the past decade.^{36,37-39} Fat grafting for reconstructing the breast mound or for correcting subtle irregularities (such as camouflaging the edge of an implant) addresses not only the problem area but also may reduce an overweight donor region such as the abdominal wall. Transferring large volumes of estrogen-producing fat to the growing mammary gland has an unknown effect on oncologic risk. However, large studies of adult cancer patients have failed to demonstrate an increase in breast cancer risk after fat transfer.³⁶

Fat grafting has been used to correct breast hypoplasia and asymmetry and to camouflage underlying chest wall asymmetries.⁴⁰ It also effectively corrects tuberous breast deformities⁴¹ (Fig. 60-11). A benefit of fat grafting is that the procedures can be performed in series, allowing gradual expansion of the skin envelope, which leads to a more natural shape that is not achievable with traditional implant augmentation. Reconstruction for breast asymmetries can begin at a younger age, as soon as patients express an interest in surgery; the lipofilling may be tailored to keep pace with the normally developing breast. This has psychological advantages for patients who might otherwise be encouraged to wait with an uncorrected deformity until breast maturity.

In our practice, the survival rate of fat grafts in pediatric patients has been high compared with rates in adult patients. This allows dramatic correction in two to three operations but may cause problems in patients who subsequently gain weight, and breast reduction may be required in severe cases. In most patients, however, the increase in overall body fat with adolescent growth allows a better correction of the deformity as the fat expands beyond what was surgically transferred.

Excision

Polythelia is best treated with simple excision of the accessory nipple or nipple-areola complex. Typically, when this is performed before puberty, no glandular breast growth occurs in the area, but periareolar hair follicles may be present. If multiple nipple-areola complexes are present on the breast itself, determining which complex is associated with glandular/ductal tissue can be challenging. An MRI may be needed to determine which nipple-areola complex to preserve. Breast reduction techniques can be used to reposition the areola appropriately.

Polymastia is treated with excision, usually with excellent cosmetic results. The most common presentation of polymastia is bilateral axillary breast tissue without duplication of the nipple-areola; this is easily excised with an axillary incision. Follow-up is recommended because of the possibility of developing cancer in retained breast tissue at the excision site. When polymastia is present on the thorax, both breasts are usually relatively hypoplastic, and the inframammary fold may be asymmetrical. Resection of one nipple-areola with preservation of the associated breast tissue allows repositioning of that tissue so that the breast volume can be preserved for improved symmetry.

Giant fibroadenomas that are small can be excised directly; however, larger ones may distort the breast and require breast reduction techniques.⁴² The timing for surgery is based on the onset of the rapid growth phase of the fibroadenoma; surgical excision is often necessary before breast development is complete because of the gross discrepancy in breast size (see Fig. 60-6).

Treatment of Gynecomastia

Gynecomastia merits treatment when glandular enlargement has been present for more than a year. At this point, the breast tends to become fibrotic and is less likely to resolve spontaneously. Even mild gynecomastia has been found to have significant negative effects on psychosocial well-being.⁴³ If possible, surgical correction before the development of areolar enlargement and skin redundancy is preferable. Ultrasonic liposuction (USL) alone is effective in many patients with grades I and IIA gynecomastia. Mild skin excess will often self-correct after USL. We prefer to use a semicircular, periareolar incision for glandular resection, combined with UDL for grade IIB and grade III gynecomastia. Before the advent of USL, incisions that were used to excise excess skin resulted in unacceptable chest wall scars. USL has allowed increased breast volume reduction without an added scar burden. A USL trochar is introduced through a small stab incision in the proximal anterior axillary line; this provides access to tissue not directly excised through the periareolar incision.^{1,2} Contour irregularities secondary to edema and seroma usually resolve without additional intervention¹ (Fig. 60-12). In patients with persistent skin excess, a circumareolar incision may be required to resect skin; however, this is only done as a secondary, staged procedure. In patients with very severe glandular enlargement and skin excess, especially with marked enlargement of the areola and ptosis, good results can result with a breast amputation by placing the scar at the inferior edge of the pectoralis major muscle, with free grafting of the nipple-areola complex (Fig. 60-13).

Fig. 60-12 **A**, This adolescent male had gynecomastia. **B** and **C**, He is shown postoperatively after glandular excision with a semicircular, periareolar incision and USL. No skin was excised.

Fig. 60-13 This male patient with gynecomastia underwent a glandular excision with an inframammary approach and free nipple grafting.

Breast Reduction

Patients with macromastia often present with debilitating back, neck, and shoulder pain and have frequently had to curtail athletic activities; breast reduction during adolescence may be warranted for selected cases.^{44,45} A variety of breast reduction techniques can provide good results. We prefer an inferior pedicle technique with a central mound to preserve blood supply and sensory innervation to the nipple. Revisions subsequent to continued breast growth are not usually required. For girls with smaller degrees of hypermastia in whom a vertical reduction technique may be a reasonable option, we prefer to delay surgery until developmental maturity. Often, patients with Poland syndrome or unilateral hypoplasia have an overly large breast on the more normal side.

Fig. 60-14 This patient underwent serial fat grafting for correction of a burn scar deformity. **A** and **B**, Preoperative images. **C** and **D**, She is shown after two sessions of fat grafting. (Courtesy of David A. Billmire, MD, FACS, FAAP.)

Depending on the patient's preference, reduction or mastopexy may be an appropriate symmetry procedure, but this should be delayed until breast growth is complete.

Treatment of Deformational Breast Anomalies

Depending on the deformity, either reduction or augmentation techniques may be required. Burn deformities respond well to tailored reconstructive techniques, including scar release, local flaps, skin grafts, and tissue expansion.^{46,47} Fat grafting may be particularly useful in burned or scarred breasts in restoring volume and releasing tethered scars⁴⁸ (Fig. 60-14). Mastopexy techniques with various pedicles can help to reposition the breast mound or nipple-areola complex. Careful attention to the degree of underlying chest wall asymmetry is important to obtain proper results in patients with scoliosis or pectus deformities.

CONCLUSION

Pediatric breast deformities are relatively common and wide-ranging in presentation. Categorizing these anomalies into the broad groups of hypoplastic, hyperplastic, and deformational facilitates discussion about causes and treatment options. Hypoplastic anomalies require augmentation mammoplasties, whereas hyperplastic breast abnormalities benefit from a variety of reduction

techniques. Autologous fat grafting is a new technique that allows earlier, staged reconstruction and precise correction of volume deficiencies. Careful consideration of surgical timing and the need for staged operations aids in anticipating and optimizing clinical outcomes.

KEY POINTS

- Pediatric breast abnormalities are relatively common.
- Congenital cases can be diagnosed early.
- Surgical treatment is usually delayed until adolescence.
- Pediatric breast abnormalities can be categorized as hypoplastic, hyperplastic, or deformational.
- Hypoplastic abnormalities have the following characteristics:
 - They are less common than hyperplastic abnormalities.
 - They require breast augmentation.
 - Implant augmentation or tissue transfer should be delayed until breast growth is complete, whereas fat grafting can begin as soon as a patient requests correction.
- Hyperplastic abnormalities have the following characteristics:
 - They are more common than hypoplastic abnormalities.
 - They require breast reduction.
 - Symptomatic patients may require surgery before breast development is complete.
- In patients with deformational abnormalities, contralateral symmetry procedures should be performed when breast growth is complete.

Hypospadias

Devon C. Snow-Lisy • Seth A. Alpert • Earl Y. Cheng

he word *hypospadias* derives from the Greek words *hypo* (under) and *spadon* (a rent) and describes a condition in which the urethral meatal opening is proximal to the normal orthotopic location of the urethral meatus at the tip of the glans penis. Historically, the correction of hypospadias has been a challenging problem for surgeons. Galen, a physician to the gladiators in Rome, described a partial penectomy, that is, resection of the penis distal to the meatus, as a surgical treatment of this disease.¹ Since then, hypospadias corrective surgery has evolved and has become more sophisticated as surgical techniques and instrumentation have improved. More than 300 procedures for hypospadias repair have been described. Many of these are modifications of techniques promoted by predecessors. This chapter discusses the pertinent anatomy, diagnosis, and classification of hypospadias. The most common current techniques for surgical correction in pediatric urologic and plastic surgery practice are presented.

A host of genetic and environmental factors have been linked to hypospadias, suggesting a multifactorial cause. The genetic basis will be better understood as genetic testing becomes more common and several potentially influential genes and polymorphisms are further evaluated² (Box 61-1).

Endocrine dysfunction, including estrogen effects, a failure of androgen stimulation caused by incorrect timing of hormone production, an insufficient androgen supply, or end-organ receptor malfunction, is thought to be the most common underlying pathway toward the development of hypospadias. The incidence of hypospadias varies with geographic region and appears to be increasing. Although the increase was initially thought to be caused by an increased detection of minor forms of hypospadias, Canon et al³ recently described an increase in the prevalence of all forms (coronal/distal, midpenile/subcoronal, and perineal/proximal penile) of hypospadias in Arkansas. The overall rates of hypospadias increased from 6.69 per 1000 (from 1998 to 2002) to

8.10 per 1000 (from 2003 to 2007).³ No clear reasons for these increases are evident; however, increased reporting of hypospadias, changes in genetic susceptibility, increased maternal age, improved survival of low-birth-weight infants, and environmental exposures may have an impact.³

PERTINENT NORMAL AND ABNORMAL ANATOMY

There are important functional and cosmetic reasons for considering surgical correction of hypospadias. Relocation of the urethral meatus to the tip of the penis facilitates a straight urinary stream, allowing a child to stand to void.⁴ It helps to improve semen deposition, which can affect fertility potential. This is most significant for the more severe forms of hypospadias. The associated chordee (an abnormal curvature of the penis) is corrected by orthoplasty in which the penis is straightened, improving sexual function and vaginal penetration later in life.⁵ Although long-term results have shown that patients with corrected hypospadias are more likely to be less satisfied with their penile appearance, they are as sexually active as controls.⁴ With hypospadias correction, the cosmetic appearance of a child's genitals resembles that of a normal circumcised penis. In selected cases, the foreskin can be preserved if an uncircumcised appearance is desired.⁶

EMBRYOLOGY

Hypospadias occurs when the process of normal urethral development is interrupted, and the urethral meatus does not reach its orthotopic location at the tip of the glans. The formation of the urethra begins at approximately 4 weeks of gestation, when the urorectal fold forms and divides the cloacal membrane into an anterior urogenital sinus and a posterior rectum.⁷ The urethral plate can be seen as a thickening of the anterior wall of the endodermal cloaca.⁸ Simultaneously, paired swellings anterolateral to the cloacal membrane become visible and fuse into a midline genital tubercle at 6 weeks of gestation.⁷ The lateral mesoderm forms urethral and genital folds. The urogenital sinus elongates onto the ventral surface of the phallus to the level of the corona and forms the urethral groove. The walls of the urogenital sinus join to form the endodermal urethral plate on the floor of the urethral groove. The groove deepens and forms the anterior urethra. Under the influence of testosterone, the fetal phallus elongates, and the urethral groove extends to the level of the corona. The urethral folds unite at the midline, closing the urethra and

forming the median raphe of the scrotum and penis. The glans closes over the urethral groove, and the underlying epithelial cells tubularize and form the glandular urethra, which grows proximally to join the penile urethra.⁹ The preputial skin forms as a ridge that gradually grows to enclose the glans circumferentially. A defect associated with hypospadias is deficient foreskin ventrally, resulting in a dorsal hood.⁷

Chordee is frequently associated with hypospadias. Glenister,⁸ in his extensive anatomic study of urethral plate and phallic development in fetuses, found that penile curvature is a normal stage in embryologic development; this finding suggests that chordee may result from an arrest of genital development at an early embryologic stage. In hypospadias, the severity of chordee parallels the severity of the defect of the urethral plate. Thus the more proximal forms of hypospadias are associated with more severe chordee.

CLASSIFICATION

Traditionally, hypospadias has been classified based solely on the location of the hypospadiac urethral meatus, with the following general categories: distal shaft (anterior urethra), midshaft (midurethra), and proximal shaft (posterior urethra)¹⁰ (Fig. 61-1). Recently, a new grading schema was proposed qualitatively describing not only the location of the meatus but also the character of the glans and chordee of the shaft, and it has been shown to correlate with the risk of postoperative complications¹¹ (Table 61-1).

Fig. 61-1 Hypospadias is traditionally classified by the anatomic location of the urethral meatus.

Table 61-1 Glans-Urethral Meatus-Shaft* Scoring Criteria for Hypospadias

Glans Score (G)	
Glans good size, healthy urethral plate, deeply grooved	1
Glans adequate size, adequate urethral plate, grooved	2
Glans small in size, urethral plate narrow, some fibrosis or flat	3
Glans very small, urethral plate indistinct, very narrow or flat	4
Meatus Score (M)	
Glanular	1
Coronal sulcus	2
Mid or distal shaft	3
Proximal shaft or penoscrotal	4
Shaft Score (S)	
No chordee	1
Mild (<30 degrees) chordee	2
Moderate (30-60 degrees) chordee	3
Severe (>60 degrees) chordee	4

*This scoring system, also known as the *GMS scoring system*, incorporates traditional meatus scoring with new glans and shaft scoring.

PREOPERATIVE AND PRETREATMENT ASSESSMENT

The diagnosis of hypospadias is usually made based on the initial newborn examination. However, with improvements in prenatal ultrasound imaging, hypospadias can be diagnosed antenatally because of changes in the distal morphology of the penis, including small lateral folds corresponding to the dorsal hood, visible chordee, and, rarely, an abnormal fetal urinary stream.¹² More minor forms of hypospadias might not be diagnosed until adulthood. Regardless of the age of presentation of a patient with hypospadias, a full prenatal and birth history should be obtained to identify potential hormonal and familial factors and to evaluate other associated conditions. To help determine whether a patient has functional deficits, the parents are asked about the direction of their child's urinary stream and the presence of curvature of the erect or flaccid penis.

A physical examination includes assessment of the following: the degree of chordee, the size and configuration of the glans, the integrity of the ventral penile skin, the quality and depth of the urethral plate, the amount of dorsal hood foreskin, and, most important, the location of the urethral meatus. In patients with significant chordee and a disproportionately distal hypospadiac meatus, the true defect is probably more severe than the meatus location suggests. In these cases the skin overlying the urethra proximal to the hypospadiac meatus is usually overly thin and associated with a poorly formed urethra, and the true level of the hypospadiac defect is much more proximal.

A careful scrotal and inguinal examination completes the genitourinary examination. Hypospadias is associated with other genital abnormalities such as cryptorchidism (8%), hydrocele (16%), and inguinal hernia (8%).¹³ Associated malformations are more likely to occur in patients with more severe hypospadias. Patients with proximal hypospadias can have associated renal

anomalies, which can be evaluated by ultrasound imaging; however, routine imaging of the urinary tract in all cases of hypospadias is not necessary.

It is important to always keep in mind the possibility of a disorder of sex development (DSD) when evaluating a child with hypospadias. A wide range of rates (4.2% to 100%) has been reported for chromosomal anomalies in patients with both cryptorchidism and hypospadias.¹⁴⁻¹⁶ This wide range is probably the result of variances in the severity of hypospadias and cryptorchidism. In patients with proximal hypospadias, the incidence of chromosomal abnormalities is higher, and it is three times more likely if one or both of the gonads are nonpalpable.^{15,17} Conclusions about an appropriate workup for these patients are controversial based on the wide range in incidence of DSD.¹⁷ The most common DSD in these cases is mixed gonadal dysgenesis, a disorder characterized by a mosaic karyotype, a unilateral streak gonad, a unilateral testicle (frequently undescended), and persistent müllerian structures. In general, a good rule of thumb is to perform a urologic and an endocrine workup in all patients with hypospadias and a nonpalpable testicle, because some conditions may have serious consequences if not identified early. A classic example of this is congenital adrenal hyperplasia caused by 21-hydroxylase deficiency. These patients can die of salt wasting caused by ineffective glucocorticoid and mineralocorticoid synthesis. The phenotype of these patients depends on the severity of the associated excess androgen production. Those with a normal female karyotype have nonpalpable gonads and a phenotype ranging from severe hypospadias to a fully formed phallus.

NONSURGICAL AND SURGICAL TREATMENT OPTIONS

As mentioned previously, relocating the urethral meatus to the tip of the glans facilitates the production of a straight urinary stream and the deposition of ejaculate within the vaginal fornix. Correcting the associated chordee improves the dynamics of vaginal penetration during intercourse and allows the patient to stand while voiding. Finally, approximating the penile appearance to other males is an important cosmetic factor that can have psychosocial implications later in life and should be addressed when counseling a family regarding the need for hypospadias surgery. In the absence of cosmetic or significant functional deficits, some mild forms of hypospadias do not necessarily “need” surgical correction. Other than issues with sexual function secondary to chordee, a recent survey showed that adult men with mild, untreated hypospadias had no deficits in their fertility, urinary function, quality of life, or satisfaction with the cosmetic appearance of their penis, compared with controls.⁵

Hypospadias surgery has no contraindications other than medical fitness to undergo general anesthesia. Proper, informed consent can only be obtained after thorough counseling regarding the risks and benefits of corrective surgery and the expected functional and cosmetic results of surgery. Hypospadias is a surgical disease, and presently no specific nonsurgical treatments are available.

PREOPERATIVE AND PRETREATMENT PLANNING

Timing of Surgery

The optimal timing of hypospadias repair is controversial. Most hypospadias surgeons think that the ideal patient age for an elective repair of hypospadias is 6 to 12 months of age.¹⁸ By 4 to 5 months of age, the anesthetic risk for infants has decreased, especially when the procedure is performed by an anesthesiologist with pediatric experience, and proper monitoring techniques are used. Studies have shown that the psychological effect of surgery on children 1 to 3 years of age is increased.¹⁸ Therefore emotional distress from genital surgery is probably lower in younger patients. The size and quality of the genital tissues after 6 months of age are usually adequate for

hypospadias repair. Conversely, a recent study reported no difference in long-term psychological adjustment, health-related quality of life, and surgical outcomes in boys who had undergone surgery before or after 18 months.¹⁹ Bush et al²⁰ and Snodgrass et al²¹ compared the complications of hypospadias repair in older children and adults after tubularized incised plate repair (TIP) urethroplasty with those in younger children and found no difference.

In one survey, 78% of pediatric urologists used preoperative hormonal stimulation in patients with proximal hypospadias and in patients with a microphallus and/or a reduced glans circumference or urethral plate.²² Androgen stimulation in the form of human chorionic gonadotropin injection, parenteral testosterone injection, dihydrotestosterone transdermal gel, and topical testosterone cream (2%) increases the size of the penis and the vascularity of the tissues. However, preoperative hormonal stimulation has potential downsides, with basic science research showing a negative impact of androgens on wound healing, potential exposure of the parents to topical hormonal therapies, patient pubic hair growth, aggressive behavior, and potential patient linear height and bone age changes.²³ The current literature does not report the risk-benefit ratio of preoperative hormonal stimulation. In a recent systematic review, Wright et al²³ showed a non-significant, increased risk of surgical complications in patients who underwent preoperative hormonal stimulation (OR 1.67; CI 0.96-2.91).

In conclusion, current indications for preoperative hormonal stimulation include children with proximal hypospadias, microphallus, and/or reduced glans width or reduced urethral plate. In most cases of routine distal or midhypospadias, hormonal stimulation is not indicated. In our practice, we utilize a 2- to 3-week period of hormonal stimulation to take advantage of the improved vascularity and tissue growth, and we stop the medication 1 week before surgery, thereby theoretically limiting the acute changes related to hormonal stimulation and its negative effects on wound healing.

SURGICAL TECHNIQUE

The surgery is performed with the child under general anesthesia. At many institutions, the anesthesiologist or the surgeon routinely performs a caudal epidural anesthetic block for pain control perioperatively. Alternatively, a local penile nerve block is performed rather than a caudal block. This prevents the possible penile engorgement seen with caudal blocks and potentially decreases the risk of postoperative complications, as Kundra et al²⁴ reported in a randomized trial. For the duration of the procedure, the child is positioned supine on the operating table, with the legs slightly abducted and flexed at the knees. All pressure points are carefully padded. A routine cystourethroscopy is not generally performed simultaneously unless indicated for other reasons.

To ensure precise placement of sutures and gentle handling of fine tissues, optical magnification during hypospadias surgery is the rule. Although most surgeons find that surgical loupes with magnification of 2.5× or higher are satisfactory, an operating microscope can be used. Intraoperative bleeding during hypospadias surgery can be minimized by intermittent use of a small tourniquet applied to the base of the penile shaft. At our institution, we have found that a thin rubber band and a hemostat (clamped over a dental roll that is positioned ventrally over the proximal urethra for protection from inappropriate compression from the rubber band) are very useful for this purpose. Alternatively, some surgeons prefer to inject the tissues with epinephrine solution (1:200,000) to prevent excessive bleeding during surgery in the well-vascularized glans and penis.

The specific surgical technique used for hypospadias correction depends on several important factors that surgeons must evaluate preoperatively and intraoperatively. These include the location of the hypospadiac meatus; the severity of the chordee; the width, depth, and health of the urethral plate; the quality of the penile shaft skin; and the presence and amount of dorsal hood tissue. The principal techniques for distal, midshaft, and proximal forms of hypospadias are discussed and illustrated in this section.

In the past, surgeons preferred to stage hypospadias and associated chordee correction with two or more procedures. More recent technical advances have allowed single-stage repairs in most typical cases of hypospadias. Presently, single-stage repairs are the benchmark for distal and most midshaft hypospadias. For patients with proximal hypospadias, especially those associated with severe chordee, whether a single-stage or a two-stage procedure is more appropriate is controversial. The pros and cons of each of these approaches are discussed in the following sections.

Distal Hypospadias

Distal hypospadias is defined as a meatus proximal to the coronal sulcus of the glans (subcoronal), at the sulcus (coronal), or distal on the glans. It is not located at the orthotopic position on the tip (glanular). Usually, the meatus is subcoronal, the associated chordee is mild, and the major goal of surgery is to produce a functional distal urethra. Currently, the most commonly used surgical procedures to correct distal hypospadias include a meatoplasty and glanuloplasty (MAGPI); a flip-flap repair, also known as a *Mathieu repair*; and a tubularized incised plate (TIP) urethroplasty, also known as a *Snodgrass repair*.

Duckett²⁵ originally described the MAGPI procedure¹⁰ for correcting distal hypospadias without chordee (Fig. 61-2). Essentially, the hypospadiac meatus is incised in a longitudinal fashion and closed transversely, that is, in the fashion of Heineke-Mikulicz. The penile skin is degloved circumferentially, and incisions are made into the glans ventrally to create glans flaps. The flaps are brought together proximal to the neomeatus, which has the effect of advancing the urethra and neomeatus distally. Finally, penile skin is reapproximated to the glans collar. An advantage of this technique is that no formal reconstruction of a neourethra is necessary; thus the likelihood of a fistula formation is extremely low. In a few, carefully selected patients, a MAGPI repair provides a very nice functional result. However, in most patients the cosmetic result is less than satisfactory, with a flattened glans and meatal retrusion. Therefore, at most centers, this is not the preferred method for repairing routine cases of distal hypospadias.

The flip-flap technique (or Mathieu technique)²⁶ uses a midline meatal-based flap of skin on the ventral penile shaft to form the anterior wall of the neourethra (Fig. 61-3). The glans is incised

Fig. 61-2 The MAGPI procedure. A circumcising incision is made, the urethral meatus is incised longitudinally and closed transversely, advancing it distally in the manner of Heineke-Mikulicz. The glans flaps are reapproximated proximally to complete the repair.

Fig. 61-3 The flip-flap (or Mathieu) repair. A midline skin flap is created from the ventral penile skin and rotated to create the neourethra distally. A vascularized dorsal dartos flap is used to cover the repair, and the remaining skin is used for penile shaft coverage.

laterally on either side of the urethral plate, and the flap is pivoted distally to create the neourethral tube. The suture lines are covered with a vascularized subcutaneous flap harvested from the preputial and shaft skin before the glanuloplasty. The advantages of the Mathieu technique are that it is not technically demanding, it is highly successful, and the suture lines do not overlap, which decreases the risk for fistula formation. Disadvantages include the variability of the blood supply to the ventral flap, which can potentially cause flap necrosis or fistula formation. Another disadvantage is the cosmetic appearance of the neomeatus, described as rounded and horizontal or like a “fish mouth,” as opposed to the desired slitlike meatus.²⁷

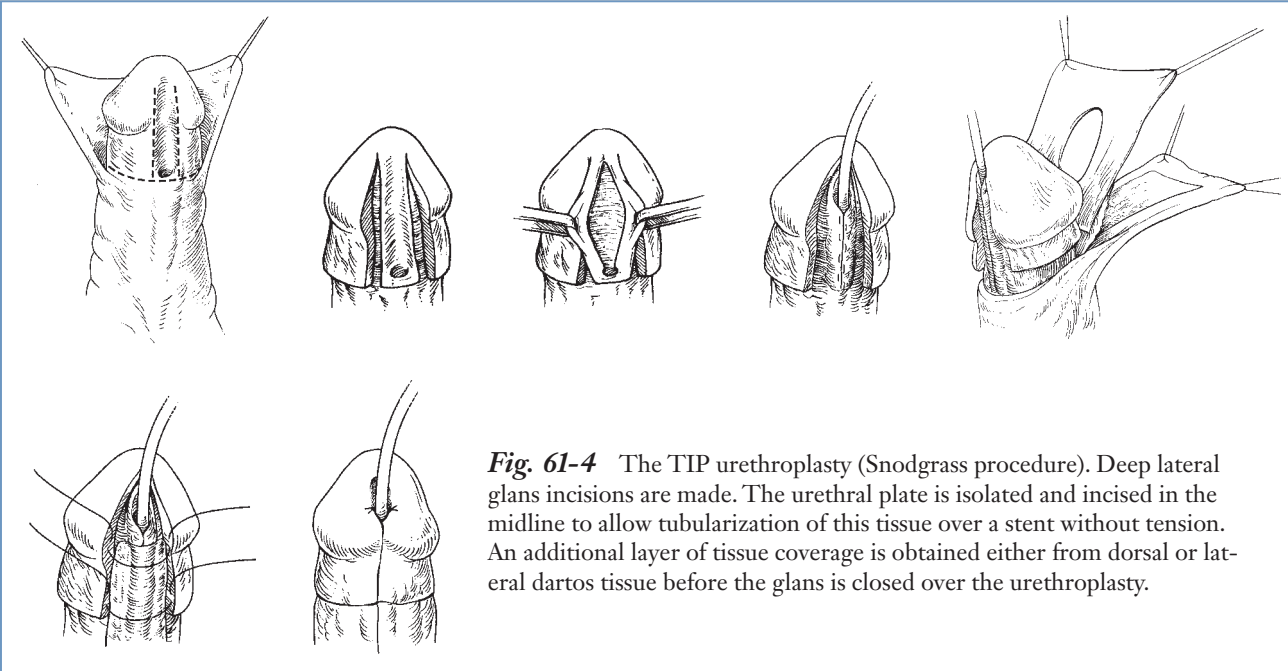

Fig. 61-4 The TIP urethroplasty (Snodgrass procedure). Deep lateral glans incisions are made. The urethral plate is isolated and incised in the midline to allow tubularization of this tissue over a stent without tension. An additional layer of tissue coverage is obtained either from dorsal or lateral dartos tissue before the glans is closed over the urethroplasty.

TIP urethroplasty is based on a modification of Thiersch-Duplay urethroplasty, which incorporates incising the urethral plate and reconstructing the urethra by tubularization of the urethral plate in situ. Rich et al²⁸ originally described incising the urethral plate in a variety of repairs. Snodgrass²⁹ popularized the longitudinal incision of the urethral plate specifically in association with the Thiersch-Duplay repair. This incision of the urethral plate avoids the potential problems with the Thiersch-Duplay urethroplasty, specifically, a glans that is disproportionately small in relation to the penile shaft and a glans closure that is too tight. This theoretically decreases the risk for dehiscence and fistula. Incision of the plate allows a tension-free anastomosis and decreases the need to incorporate surrounding glans tissue in the urethral reconstruction. Reclosure of the urethral plate incision postoperatively and urethral strictures are a concern. However, basic science research demonstrated that the area of incision reepithelializes quickly, and a meta-analysis comparing the flip-flap to TIP urethroplasty showed no significant differences in fistula development, meatal stenosis, or wound dehiscence.^{30,31}

A TIP urethroplasty, also known as the Snodgrass procedure²⁹ (Fig. 61-4), involves tubularization of the urethral plate using flaps created from parallel, longitudinal incisions in the glans; this maneuver creates glans wings for closure. The Snodgrass modification consists of a deep midline incision in the urethral plate, from the hypospadiac meatus to the tip of the glans. The urethra is closed ventrally in two layers, and the epithelium is inverted. The urethral meatus has a normal, vertical, slitlike appearance. One of the potential drawbacks to this procedure is that all suture lines overlap in the midline. Therefore many surgeons routinely cover the repair with a vascular, deepithelialized flap from either the prepuce or lateral ventral tissue.³² This practice was recently debated after a prospective randomized trial showed no difference in complications between the use of a dartos flap and a flapless TIP repair³³ (Fig. 61-5). Regardless of flap utilization, the TIP procedure provides optimal functional and cosmetic results, and it is our procedure of choice for repairing most cases of distal hypospadias.

Fig. 61-5 Harvesting a vascularized flap. **A**, A vascularized dartos flap is harvested from the subcutaneous tissue of the dorsal penile skin and preputial skin. **B**, The flap is rotated on its pedicle to provide ventral coverage.

Of the multiple surgical options available to correct distal hypospadias, the optimal procedure for a particular patient is operator dependent and individualized to the patient's particular anatomy. Currently, the trend is toward using a TIP urethroplasty as the operation of choice for distal hypospadias, primarily because it provides excellent overall cosmetic and functional results.³⁴

Foreskin preservation, or preputial reconstruction, is possible with hypospadias repair. The role of preputial reconstruction in hypospadias is controversial and currently debated. Some surgeons are concerned that preputial reconstruction may increase complications because of alterations in the blood supply to the urethral reconstruction and because of an inadequate amount of skin for reconstruction, which increases the risk of phimosis. The technique for foreskin reconstruction involves layer-by-layer reconstruction. An incision is made along the lateral edges of the hooded foreskin, and the prepuce is divided into three layers. The foreskin is sutured in the midline in three layers; the first two layers (the inner prepuce and dartos fascia) are approximated in a continuous fashion and the outermost layer (outer prepuce) in an interrupted fashion.³⁵ The reported complication rates for preputioplasty vary significantly. However, in a recent report in which preputioplasty was offered only to patients with favorable anatomy, only 3.9% required a secondary circumcision.³⁵

The decision to preserve the foreskin should be made by the parents. Informed consent is obtained after parents are provided with objective data regarding the potential benefits of preputioplasty and complication rates, which vary depending on the severity of the hypospadias and the foreskin anatomy. This is weighed, along with the parents' cultural/personal desires for an uncircumcised appearance, to determine the appropriate surgical intervention.

Midshaft Hypospadias

Hypospadias on the midshaft portion of the penis is usually associated with more significant chordee than distal hypospadias. Therefore correction of chordee is a much more significant component of the surgical procedure. (This portion of the procedure is discussed in detail in the following section on proximal hypospadias). TIP urethroplasty is still an excellent option for midshaft hypospadias when the integrity of the urethral plate is good. In some cases of more severe

Fig. 61-6 The onlay island flap. A vascularized island of skin with a pedicle is harvested from the inner preputial skin and anastomosed to the urethral plate with two lateral suture lines. The glans is reapproximated over the closure, and the penile skin is closed to complete the repair.

midshaft hypospadias, the urethral plate is either too narrow or not supple enough for tubularization without tension, even after a deep incision is made in the base. In such cases, alternative techniques should be considered. However, patients with an adequate urethral plate achieve good functional and cosmetic results with a low rate of complications.³⁶

The other common technique employed for midshaft hypospadias²⁶ is an onlay island flap urethroplasty (Fig. 61-6). The urethral plate is preserved as the posterior urethral wall. The anterior urethral wall is created from a strip of skin usually obtained from the inner preputial skin of the foreskin, harvested with its native blood supply. A vascularized flap of penile skin may alternatively be used. The flap is rotated ventrally and anastomosed onto the urethral plate with two lateral running suture lines. Glans wing flaps are created and closed in the midline. The penile skin is closed primarily, or the ventral penis is resurfaced using skin flaps from the dorsal prepuce (Byars flaps). The onlay island flap has been shown to have good cosmetic results; however, it increases the risk for a urethral diverticulum. This is probably the result of poor tissue support for the anterior neourethral wall, which may promote outward ballooning of the neourethra.³⁷ In a recent systematic review and meta-analysis comparing the onlay island flap procedure with TIP urethroplasty, the onlay island flap repair had relatively few complications, especially in patients with little or no chordee.³⁷

Proximal Hypospadias

When the hypospadiac meatus is in a more proximal location (penoscrotal, scrotal, or perineal), corrective surgery is less straightforward and more challenging. Not only is the length of urethra requiring reconstruction greater, but also these patients generally have a greater degree of chordee, and the urethral plate may be fibrotic, narrow, or nonexistent. Depending on a patient's characteristics, the hypospadias can be repaired in several surgeries (staged) or all at once (single-stage). A single-stage approach corrects chordee and builds a urethral tube extending to the glans in one surgery. A staged repair corrects the chordee and provides a foundation of tissue on the urethral plate that will be used to complete the repair 6 to 12 months later.

Adequate correction of the chordee (orthoplasty) is the first step in staged and single-stage repair. The initial approach to orthoplasty is to deglove the penile skin and aggressively dissect and excise abnormal fibrous chordee tissue from the corporal bodies. In some cases this dissection alone is sufficient to straighten the penile shaft. To assess the degree of residual chordee after this dissection, an artificial erection is created with a tourniquet, as described previously for control of blood loss. Saline solution is injected into one of the corporal bodies with a butterfly needle. Persistent chordee (greater than 20 to 30 degrees) is corrected with one of several approaches. Nesbit³⁸ described removal of small transverse strips of tissue from the dorsal surface to equalize the disparity between the surfaces (Fig. 61-7). A modification of this technique closes these longitudinal incisions horizontally with plicating sutures in the manner of Heineke-Mikulicz.³⁹ Baskin et al⁴⁰ performed anatomic studies demonstrating that the distribution of the dorsal neurovascular bundle is more laterally diffuse than previously thought, which suggests that Nesbit plication techniques could injure nerves inadvertently. He therefore proposed a dorsal plication in which a permanent plication suture or sutures are placed in the midline between the neurovascular bundles. This has proved to be an effective method of correcting moderate degrees of residual chordee. If adequate correction of chordee is possible with dorsal plication techniques,

Fig. 61-7 Chordee repair. **A**, The Nesbit tuck procedure. Vertical elliptical segments of tunica albuginea are removed from the longer, more convex portion of the penile shaft to correct the chordee. **B**, Dorsal plication. The tunica albuginea is sutured lateral to the dorsal vein and repeated as necessary to correct the chordee.

then a single-stage procedure can be considered, and the urethra can be reconstructed with one of several techniques.

Several options are available for urethral reconstruction. As mentioned previously, a TIP procedure is an option when the urethral plate is soft and supple. When the urethral plate is present but not adequate for tubularization, then an onlay flap can be used. For cases in which the urethral plate is too deficient to use with onlay flap techniques, a tubular vascularized flap can be used. Duckett^{25,41} first introduced such a flap—the transverse preputial island flap (Fig. 61-8). A

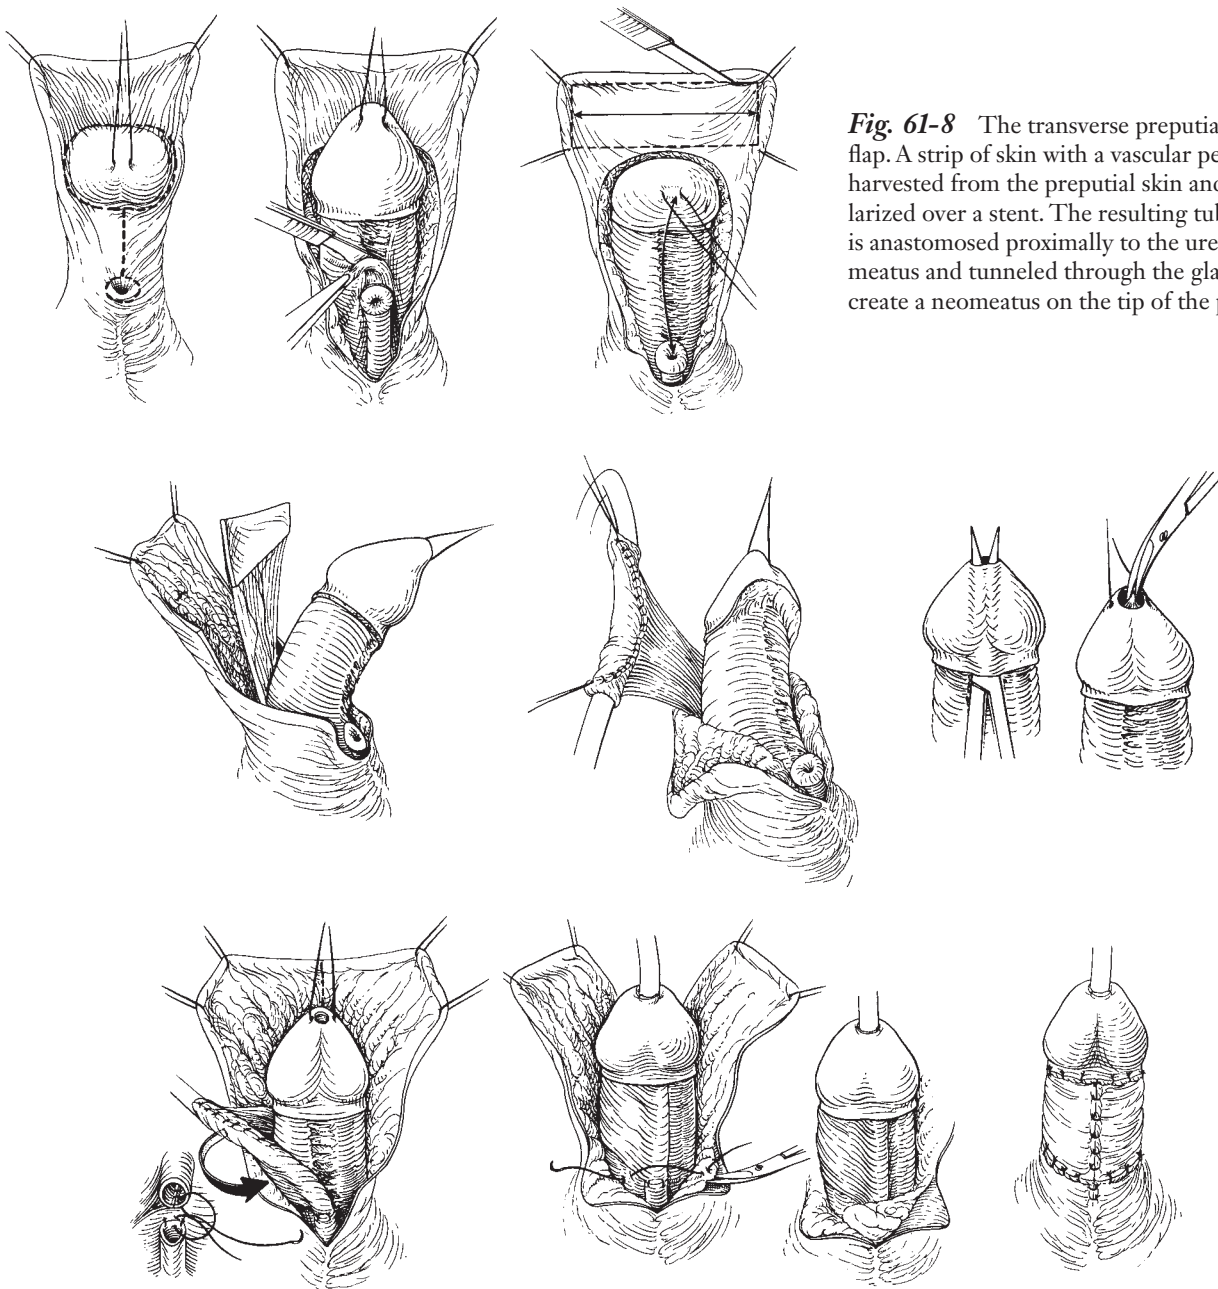

Fig. 61-8 The transverse preputial island flap. A strip of skin with a vascular pedicle is harvested from the preputial skin and tubularized over a stent. The resulting tube flap is anastomosed proximally to the urethral meatus and tunneled through the glans to create a neomeatus on the tip of the penis.

Fig. 61-9 The Koyanagi repair. Yolk-shaped incisions on the parametral penile tissues facilitate penile degloving. The chordee is corrected, and a tubularized neourethra is created using the ventral and inner preputial skin and an inverting running suture. Distal skin flaps are trimmed as necessary, and the ventral aspect of the penis is resurfaced with Byars flaps.

vascularized strip of dorsal preputial skin is tubularized over a catheter to create a neourethra between the proximal hypospadiac meatus and the tip of the glans. The width of the flap should be approximately 15 mm to roll a tube of adequate diameter. Within the glans, the tube can either be placed between flaps of glans tissue that have been created following a deep incision in the glans, or it can be tunneled through the central portion of the glans to create a neomeatus at the tip.

Koyanagi et al⁴² developed an alternative approach to a single-stage repair of hypospadias that uses flap and tubularization techniques to form the urethra. After the chordee is adequately corrected, a meatal-based preputial flap is used (Fig. 61-9). This repair is referred to as a *manta-wing flap procedure* because of the appearance of the skin flaps used to form the urethra. Regardless of the type of urethroplasty performed, covering the repair with a vascularized flap is essential

Fig. 61-10 Corporal body grafting. A diamond-shaped wedge of corporal body tissue is removed ventrally and grafted with replacement material to correct severe chordee.

to reduce the risk of breakdown and fistula formation. Similar to correction of midshaft hypospadias, this tissue can be harvested from the surrounding dartos layer of the penis or from the tunica vaginalis, which is harvested from the spermatic cord and the associated testis.⁴³

When significant chordee cannot be appropriately corrected with dorsal plication techniques, then a staged approach is performed. Dividing the urethral plate at the area of maximum curvature and dissecting it away from the corporal bodies allows resection of all remaining fibrotic and dysgenetic tissue contributing to the chordee. In some cases this maneuver sufficiently reduces the chordee to allow correction with a dorsal plication. However, in most cases complete correction of the residual chordee requires corporal body grafting (Fig. 61-10). A deep ventral incision at the area of maximal curvature is made within the corporal bodies, extending to the lateral border of the dorsal neurovascular bundle on each side. This results in a diamond-shaped defect that can be grafted with either a free graft of dermis (from a non-hair-bearing portion of the body), small intestinal submucosa, or tunica vaginalis.⁴⁴⁻⁴⁶ Small intestinal submucosa, a xenograft material, has proved useful for corporal body grafting. It is an off-the-shelf material that requires no donor tissue, facilitates corporal body regeneration, and is as effective as donor tissue from the host.⁴⁶

Once corporal body grafting is completed, skin flaps are rotated ventrally to create a new urethral plate that will be tubularized into a neourethra at the second stage of repair. Different types of flaps can be used for ventral penile skin coverage. The skin is typically made up of a combination of penile shaft and/or preputial skin. Regardless of the type of skin used, adequately preserving the blood supply to the flap and tailoring it along the ventral penis to create a flat plate of skin without redundancy are critical. This facilitates tubularization in the second stage. Skin flaps are also useful for resurfacing the ventral aspect of the glans when the native glandular urethral plate is inadequate.^{47,48} Six to twelve months later, at the second stage, a neourethra is created by incising a 15 mm strip of tissue at the ventral midline, which is then tubularized to the tip of the glans. The lateral skin edges are mobilized, and the remaining tissue is closed over the repair in at least two layers.⁴⁸ Cheng et al⁴⁹ proposed a modification of the traditional staged repair in which the urethral plate is divided more proximally at the level of the hypospadiac meatus to preserve the native urethral plate. The preserved urethral plate can be used for tubularization of the distal

neourethra within the glans and distal shaft using the TIP technique at either the first or second stage⁴⁹ (Fig. 61-11). This modification appears to lower the fistula rate and overall complication rate related to the formation of a neourethra. The glans has a more normal appearance with this technique. This modification is appropriate only in cases in which the native urethral plate in the glans is adequate for primary closure. When the native urethral plate in the glans is inadequate, the distal urethra can be repaired with skin flaps, with good cosmetic results.⁵⁰

Fig. 61-11 Proximal division of the urethral plate. **A**, An incision is made along the inner preputial skin to fashion a mucosal collar, and a U incision is made along the penile shaft, preserving the urethral plate. The base of the U incision is behind the hypospadiac meatus. **B**, After the chordee is corrected, if division of the urethral plate and staged repair will be necessary, the plate is divided proximally at the level of the original hypospadiac meatus. **C**, Chordee tissue, fibrous tissue along the ventral penis, is further dissected and resected. This usually results in distal migration of the urethral plate and proximal migration of the hypospadiac meatus. Correction of chordee is completed with dorsal plication and/or corporal body grafting (a diamond-shaped graft) at the point of maximal curvature. **D**, The urethral plate is undisturbed, and Byars flaps are used to fill the gap between the plate and hypospadiac meatus. The plate is tubularized at the second stage. **E**, Alternatively, the urethral plate is incised and tubularized using the Snodgrass technique at the first stage repair. **F**, Byars flaps are used to cover the defect between the hypospadiac meatus and the tubularized urethral plate.

Reoperative Hypospadias

When primary hypospadias repairs (single-stage or staged) fail or break down, subsequent attempts at repair can be very difficult. When the urethral plate is still intact or the surrounding tissue appears viable and healthy, a repeat repair with one of the techniques described previously can be successful. However, in patients who have undergone numerous failed attempts at repair, the anatomy and native penile tissue are often distorted and the blood supply compromised. Predicting the tissue reaction with subsequent surgery is challenging. These patients are known as *hypospadias cripples* and usually have a severe deformity of the penis.⁵¹ These are among the most difficult and technically challenging cases for hypospadias surgeons. Repairs must be individualized based on the tissue available for use and the functional needs and desires of the patient.

For all reoperative hypospadias patients, the degree of residual chordee is corrected first. Next, tissue available for creating a new urethra is assessed. Well-vascularized penile skin that can be used is usually the first choice for a urethral substitute. When the urethral plate and/or local penile skin is not suitable because of fibrosis and scarring, an alternative source of tissue is needed. Historically, surgeons have employed numerous free grafts with variable success, including non-hair-bearing skin and bladder mucosa.^{52,53} Most recently, buccal mucosa was found to be the most successful tissue for use as a free graft.⁵⁴⁻⁵⁶ As a urethral wall replacement, it has superior properties that promote neovascularization and histologic features that most closely resemble native urethral tissue, compared with other free grafts.⁵⁵ Harvesting buccal mucosa from the inner cheek and/or lower lip is a relatively simple procedure with minimal morbidity. Even large grafts can be harvested without closure of the defect within the oral mucosa, because the oral mucosa regenerates quickly and rarely leaves a constrictive defect.⁵⁷ In patients with a viable urethral plate, a buccal mucosa graft can be placed on the plate in an onlay fashion as a single-stage procedure. Because this is a free graft and requires neovascularization, coverage with well-vascularized tissue such as a tunica vaginalis flap is essential for success^{58,58a} (Fig. 61-12).

In cases in which no healthy urethral plate is available, a two-stage buccal mucosa graft urethroplasty is employed. At the first stage, the unhealthy urethral plate and surrounding scar tissue are excised, and the buccal graft is secured and quilted to the bare penile tissue along the

Fig. 61-12 Buccal graft urethroplasty.
A, A graft of buccal mucosa is harvested from the inner portion of the cheek or the lower lip. Care is taken to prevent injury to Stensen's duct, which is adjacent to the second molar.

Continued

Fig. 61-12, cont'd **B**, Scarred unhealthy tissue is removed. The glans is split widely and the shaft skin elevated laterally to facilitate a wider well-vascularized bed for grafting. **C**, The defatted buccal graft is quilted into place from the proximal urethral meatus to the tip of the glans and the elevated lateral skin with as wide a graft as possible. **D**, A bolster is secured to the ventral aspect of the penis to improve graft take during revascularization. **E**, After 6 months the buccal mucosa is tubularized over a stent, with either dartos or tunica vaginalis flaps covering the suture line. **F**, The ventral aspect of the penis is resurfaced with Byars flaps.

ventral surface of the penis. The graft is fenestrated to decrease the risk of hematoma formation and to enhance imbibition of the graft. Six months later, after the graft develops adequate blood supply from the surrounding tissue, it is tubularized (see Fig. 61-12). Two-stage buccal mucosa urethroplasties have been shown to have greater success and superior cosmesis, compared with historical repairs for reoperative hypospadias. Long-term evaluations has shown a complication rate of 24% to 37% with no recurrent ventral curvature even in patients followed longitudinally after puberty.^{57,59,60}

POSTOPERATIVE CARE

At the completion of hypospadias repairs, most surgeons place a postoperative dressing for the phallus. The type of dressing is based on the surgeon's preference. An ideal dressing is nonadherent, provides slight compression to prevent swelling and/or to promote hemostasis, and absorbs wound drainage. At our institution, the surgical site is wrapped with a dressing of benzoin-soaked Owens gauze and then Coban secured with clear plastic meshed tape. This dressing provides gentle compression and keeps the wound clean and dry. It is left in place for 4 to 5 days and removed

in the office by a physician or nurse. Others have advocated a transparent bioocclusive dressing such as Tegaderm, silicone foam dressings, and recently, octyl cyanoacrylate (super glue).⁶¹⁻⁶³ Two studies have compared different types of dressings to no dressing after hypospadias repair.^{64,65} Both found that complications did not increase postoperatively when only antibiotic ointment (and no other dressing) was used; they concluded that a dressing was not required after routine hypospadias repairs. In contrast, some procedures are more extensive and require a great deal of dissection; therefore postoperative hemostasis is an issue. In these cases a more involved elastic dressing that places pressure on both the penile repair and the perineum may be extremely valuable.⁶⁶ Once a dressing is removed, a topical antibiotic ointment is typically applied to the penis for 1 or 2 weeks to create a barrier between the wound and the diaper and its contents while the suture lines heal.

Temporary urinary diversion with a urethral stent (6 to 8 Fr) is commonly used after hypospadias repair to direct urine to drip into the child's diaper. Stents are usually left in place for 7 to 14 days postoperatively. Types of urethral stents include a pediatric feeding tube and commercially available tubes such as the Firlit-Kluge urethral stent, the Zaontz urethral stent, and the Koyle diaper stent, all from Cook Medical. Infection is a concern with open-ended stents; however, Montagnino et al⁶⁷ found no differences in the rates of postoperative urinary tract infection when open urethral stents with double diaper techniques were used, compared with a traditional closed urinary drainage system. Stents are thought to facilitate adequate healing of the neourethra. Whether stents are needed in routine cases of hypospadias is not clear. Several studies have suggested that the complication rate is not increased when a stent is not used.^{68,69} Not only does stenting decrease postoperative urinary retention, but also some studies suggest that stenting promotes a higher success rate. It decreases postoperative urinary retention. Buson et al⁷⁰ found that complications after Mathieu repair were significantly higher (18.9% versus 4.6%) in unstented versus stented repairs, and El-Sherbiny⁷¹ reported a higher reoperation rate in patients with unstented Snodgrass repairs than in patients with stented repairs. Some surgeons advocate suprapubic urinary diversion. One randomized trial compared the use of a suprapubic catheter and a small anterior urethral catheter versus urethral urinary drainage and noted decreased bladder spasm (33% versus 0%), a lower rate of fistula (12.7% versus 2.3%), and similar meatal stenosis rates (2.4%), respectively.⁷²

Most pediatric urologists prescribe antibiotics after both unstented (60.2%) and stented (76.6%) hypospadias repairs.⁷³ This practice has been questioned because of increased focus on antimicrobial stewardship and the conflicting results of studies evaluating the benefits of routine antibiotic prophylaxis after stented hypospadias repairs.⁷³⁻⁷⁵ In a practice environment where judicious antibiotic use is required to prevent resistant microorganisms, a prospective multicenter randomized controlled trial currently enrolling patients at our institution will potentially clarify the role of antimicrobial prophylaxis after stented hypospadias.

TREATMENT OUTCOMES AND COMPLICATIONS

The overall outcome and complication rate after hypospadias repair is generally directly proportional to the length of urethra reconstructed and the overall complexity of the repair. Possible complications after hypospadias repair include bleeding or hematoma formation, infection, urethral fistula, meatal stenosis, recurrent chordee, urethral diverticulum, partial or complete urethral repair breakdown, that is, dehiscence, urethral stricture, and erectile dysfunction. The most common complications for distal hypospadias repairs include fistula (3.8% to 11.5%), meatal stenosis (0.7% to 7.7%), wound dehiscence (1.6% to 2.6%), and urethral stricture (0% to 0.7%).^{30,76} Proximal repairs have higher rates of complications, including fistula (15% to 33%), meatal stenosis (26%), chordee (18%), dehiscence (11.3% to 42.3%), urethral diverticulum (4%

to 27%), and obstructive voiding symptoms (37%).^{77,78} In general, unless immediate intervention is required to address postoperative bleeding, infection, or wound debridement, reoperation for hypospadias should be delayed for at least 6 months to allow edema and inflammation to subside and full healing to occur.

The most common complication after hypospadias repair is urethrocutaneous fistula formation. Overall fistula rates range from 3.8% to 33%.^{76,77} As mentioned previously, the more proximal the hypospadias repair, the higher the risk of fistula formation. Recent advancements in surgical technique, optical magnification, and suture material have significantly lowered the fistula rate. It is relatively uncommon for a fistula to develop in an uncomplicated repair of distal hypospadias. A variety of factors may be responsible for fistula formation, including infection, tissue ischemia, and meatal stenosis. Fistulas are most frequently apparent within the first year after the repair. However, up to 23% become evident only after 1 year of follow-up.^{79,80} They generally manifest as urine leakage from an area of inflammation or wound breakdown on the ventral surface of the penile shaft. Rarely, a small fistula will close spontaneously with observation and local wound care, but most often a formal surgical repair of the fistula is required once it fully epithelializes. Fistula repair is best performed 6 to 12 months after the initial repair to allow resolution of tissue edema and induration. Small fistulas can usually be repaired by excision of the fistulous tract down to healthy tissue, inversion of fresh edges, primary closure, and coverage with multiple layers of well-vascularized surrounding tissue. In cases in which a simple primary closure is performed, distal stenosis/stricture should be ruled out as a cause of the fistula. When this is present, a complete repeat of the hypospadias repair may be needed. Larger fistulas may require more extensive repair with the use of onlay flaps, revision of the glans closure, and/or a possible complete repeat of the primary repair if the remaining intact neourethra is stenotic or poorly formed.

Meatal stenosis that develops after a hypospadias repair is probably related to technical aspects of the neomeatus creation, for example, tension on the neomeatus is excessive, or the meatus is too narrow. Snodgrass⁸¹ described the following methods for preventing this complication in a TIP procedure: not tubularizing the neourethra too far distally into the glans, making sure that the incision of the urethral plate is deepened down near the level of the corporal bodies, and resisting the urge to extend the relaxing incision into the distal glans and the area of the neomeatus. When these recommendations are followed, meatal stenosis is relatively uncommon. In a large series of TIP repairs, the meatal stenosis rate was 1%.³² Mild forms of this complication can be treated by the parents with a short period of frequent dilation using the tip of an ophthalmic ointment tube or a small-caliber feeding tube.⁸² A topical steroid ointment can be used in conjunction with dilation to decrease edema and fibrosis. More severe or recurrent forms may require a formal meatoplasty.

A urethral diverticulum can form postoperatively as a result of distal obstruction, meatal stenosis, general laxity of the neourethral tube from redundant tissue, and/or skin that stretches more than expected. This problem rarely occurs in repairs that primarily use the urethral plate, and it is more common with long neourethras made from local skin flaps. Symptoms from diverticulum formation include ballooning of the urethral tube while voiding, dribbling of retained urine after voiding, and urethral stone formation. In patients with distal obstruction, correction

of the outflow obstruction may improve these symptoms and resolve the diverticulum when it is discovered early. However, excision and repair of the urethra is usually necessary once a diverticulum has formed.

Urethral strictures are typically found within the first year after hypospadias surgery and manifest most frequently in the area of the original hypospadiac meatus.⁸⁰ Many factors can contribute to stricture formation, including tension on the urethral tube, tissue ischemia, inappropriate formation of the neourethra, infection, trauma from instrumentation, and the use of large catheters.⁸² Symptoms include urinary hesitancy, decreased caliber of the urinary stream, straining to void, and/or infection. A diagnosis is usually made with retrograde urethrography and/or cystoscopy. Mild strictures can be managed with intermittent urethral dilation when diagnosed early. An internal urethrotomy may be helpful for short strictures without dense scar formation. Generally, most strictures will not respond to dilation or incision unless they are very mild. For strictures that recur after one dilation or incision, either excision of the stricture or a formal repeat urethroplasty is indicated.

Previously, surgeons evaluated the success of hypospadias repairs, based almost entirely on their own cosmetic and functional outcome criteria. The use of patient- and parent-reported quality-of-life outcomes and satisfaction measures is increasing. These data provide objective measures for the outcomes that mean the most to patients. Wide adoption of objective scores, such as the Hypospadias Objective Penile Evaluation score and the Penile Perception Score, will improve reporting of surgical outcomes.^{83,84} Because mild forms of hypospadias do not necessarily “need” to be repaired, these outcomes are especially important for counseling. As expected, currently reported quality-of-life outcomes are worse with more proximal/severe hypospadias. Surveys have shown decreased satisfaction with cosmetic appearance, decreased satisfaction with penile length, worse erectile dysfunction (distal: 9%, midshaft: 50%, and proximal: 72%), and impaired sexual quality of life in patients with proximal hypospadias.^{85,86}

FUTURE DIAGNOSTIC, ASSESSMENT, AND TREATMENT MODALITIES

Hypospadias is a surgical disease. In the future, the current goals of repair will endure: correcting the chordee, repositioning the urethral meatus in an orthotopic location, and creating an overall excellent cosmetic appearance of the penis. Corrective surgery for hypospadias has evolved. Recent advances include maximizing the use of a patient’s native urethral plate, an increased awareness of the importance of a second layer of coverage over the repair, and a better understanding of the abnormal anatomy. These changes have greatly improved the overall success rates, decreased complications, and enhanced the functional and cosmetic outcomes. Despite recent improvements in surgical technique, cases of proximal hypospadias continue to be a technical challenge for even the most experienced surgeons. Hopefully, further technical and surgical advancements will result in success rates more in line with current success rates for distal hypospadias. New discoveries in tissue engineering research and basic science work focusing on cellular factors important for optimal wound healing hold great promise for improving our current surgical armamentarium for hypospadias repair.

KEY POINTS

- Many types of hypospadias repair have been developed over the last several decades with varying degrees of success.
- Currently, the most commonly used repairs that lead to excellent results emphasize functional success and cosmesis.
- A successful repair should result in a straight penis with a urethral meatus properly positioned at the tip of the glans and a normal-appearing penis.
- Most routine cases of hypospadias can be performed on an outpatient basis in patients who are at least 6 months of age, with a success rate greater than 95%.
- Surgical success depends on a tension-free repair using well-vascularized tissue with additional vascularized flap coverage.
- For more severe forms of hypospadias, a two-stage repair may be needed.
- The decision to perform a one-stage or two-stage repair depends on the degree of chordee and the integrity of the urethral plate.
- In patients without an adequate urethral plate or penile skin to create a neo-urethra, including those requiring reoperative hypospadias, repair with buccal mucosa has been very successful.

Feminizing Genital Surgery in Disorders of Sex Development

Elizabeth B. Yerkes

Feminizing genital surgery for intersex conditions, or disorders of sex development in current consensus terminology,¹ has evolved tremendously over the past half century.^{2,3} As emphasis was placed on functional potential and feminizing cosmetic outcomes, technical modifications based on the gradually growing understanding of clitoral neurovascular anatomy and its likely relationship to sexual function led to the nerve-sparing techniques most commonly used today. In the middle of the last century, clitoral reduction was effectively *clitorectomy*. This was recognized as unacceptable because of the resulting difficulties with arousal. The next iteration of feminization was *clitoral recession*, with the clitoral bodies folded on themselves for concealment. Although this procedure feminized and preserved the clitoral tissues, arousal and engorgement resulted in a painful bulge in the infra-pubic and mons regions. Subsequently, over the past several decades, a more detailed understanding of the clitoral neurovascular anatomy has led to a series of modified techniques collectively called *reduction clitoroplasty*. These more contemporary techniques attempt to protect the integrity and innervation of the glans clitoris and the proximal neurovascular supply to the clitoris with the goal of preserving sexual function.

This chapter discusses the following components of feminizing genitoplasty: degloving, management of the urethral plate, management of the clitoral body, recession of the glans and creation of the clitoral hood, and labioplasty. Depending on whether vaginoplasty is undertaken in the same setting as feminizing genitoplasty or deferred, as with congenital adrenal hyperplasia, modifying the appropriation of tissue resources and minimizing future use of previously operated tissues must be considered.

PREOPERATIVE CONSIDERATIONS

The surgical approach and considerations are also applicable to male-to-female transgender feminization in adults, with the caveat that the tissues for creation of the clitoral hood and labioplasty will likely be affected by chronicity of androgen exposure and resultant tissue changes and rugation despite preoperative conversion to an estrogen environment. Nerve-sparing techniques with glans reduction and penile skin-flap vaginoplasty have been reported with good results.⁴ Some of these tissue changes may also be seen in older children and adolescents with poor medical control of congenital adrenal hyperplasia or disorders of sex development, in whom surgery is deferred until the patient can participate in the decision-making process.

The timing and indications for clitoroplasty and vaginoplasty in infants born with disorders of sex development are currently quite controversial. The 2006 “Consensus statement on management of intersex disorders”¹ suggested “surgery should only be considered in cases of severe virilization (Prader III, IV, and V) and should be carried out in conjunction, when appropriate, with repair of the common urogenital sinus.” Surgeons performing these reconstructive procedures must be well versed in the physiology of these conditions and the current controversies, practice patterns, and potential legal implications with regard to irreversible genital surgery in infants and minor children. A strong understanding of clitoral anatomy is also essential. This chapter is written as a guide for surgical concepts of feminizing genitoplasty for external structures, if reconstruction is elected after extensive counseling regarding the known (cosmetic, secondary procedures) and potentially unknown (sexual function and gender dysphoria) outcomes. Informed decision-making for surgical intervention or actively deferred surgical intervention is a highly individualized process.⁵ This chapter is written neither in support of nor in opposition to genital reconstructive procedures. As stated previously, reconstruction of the urogenital sinus to externalize the urethra and vagina as separate openings is often undertaken at the same time as the external aspects of feminizing genitoplasty. The timing is controversial primarily because of concerns regarding the need for secondary procedures, namely, secondary procedures for vaginal stenosis. If the parents do not elect external feminizing surgery during their child’s infancy, reconstruction of the urogenital sinus is also often deferred. The fine points of the various approaches to the urogenital sinus and forms of replacement vaginoplasty are beyond the scope of this chapter on external elements of feminizing procedures. Some details will be provided as relevant to surgical planning for feminizing genitoplasty.

CLITORAL ANATOMY AND NEUROANATOMY

Our current knowledge of clitoral neuroanatomy is derived from the work of Baskin and colleagues^{6,7} on sections of the human fetal clitoris, as well as their work with a hyena model of clitoral hypertrophy. The cavernous (autonomic) nerves are responsible for erectile function of the clitoris. Sensation of the clitoris is from the paired dorsal nerves of the clitoris. The cavernous nerves originate from the vaginal plexus (related to the inferior hypogastric plexus of the rectum) at the 10 o’clock and 2 o’clock positions along the anterior vagina and course along the 5 o’clock and 7 o’clock positions of the proximal urethra. The cavernous arteries travel with the nerves. The cavernous nerve and artery enter each clitoral body under the pubic arch near the union of the crura to form the clitoral body. Branches of the cavernous nerve also join the dorsal nerves under the pubic arch.⁸

The dorsal nerves originate from the pudendal nerves (somatic sensory and motor) and course along the crura and ischiopubic rami. Under the pubis at the bifurcation to the crura, the dorsal nerve maintains a lateral position. The relationship between the crura and dorsal nerve is different from the neuroanatomy in the male. Dissection between the crura and rami should be avoided in females.⁸ Dorsal nerve tissue is minimal in the midline, but nerve tissue is more notable at the

11 o'clock and 1 o'clock positions along the clitoral body. The dorsal nerve branches fan dorsolaterally but are deficient ventrally^{6,7} (Fig. 62-1). The glans clitoris has greatest innervation dorsally but minimal ventrally.⁶ In a virilized clitoris, as in patients with congenital adrenal hyperplasia, variations from normal may be expected. The hyena model suggests that the nerves may indeed course more laterally; this supports the use of ventral incisions at the stage of reduction of the clitoral body (see the section Management of the Clitoral Body).⁷

Fig. 62-1 **A**, A dorsal view of a hypertrophied clitoris in a patient with a disorder of sex development. The relationship between the nerves and pubic arch proximally is shown. The dorsal midline has no nerves, but they are concentrated dorsolaterally on each side. The nerves fan laterally. **B**, A cross-section of the clitoris. The bulk of the erectile bodies changes with the degree of virilization. The layers most pertinent to the degloving step are the dartos and Buck's fascia. In this illustration and the subsequent cross-sections, the dartos is depicted as distinct from the subcutaneous tissue, but they are effectively a single layer and envelop the superficial veins. Immediately deep to the Buck's fascia, the dorsal vein and arteries are closer to the midline of the body of the clitoris, and the nerves are more dense dorsally, present but less dense laterally, and deficient ventrally.

O'Connell et al⁹ provided important anatomic information about the true clitoral anatomy. Specifically, MRI studies in nulliparous premenopausal women revealed the natural hairpin curve of the clitoris, which results in a more caudal position of the glans relative to the clitoral body. The erectile components of the clitoral complex were clearly identified, including their relationship to the pubic arch and the urethra and vagina. The erectile complex includes paired clitoral bodies with a thin, fibrous septum distally and separation proximally to form the paired crura and paired bulbs, which nearly join ventral to the urethra and flank the urethra and vagina distally. Previous depictions of the female anatomy showed this as less defined tissue⁹ (Fig. 62-2).

Fig. 62-2 Normal pelvic and clitoral anatomy. **A**, An axial view shows the relationship between the clitoral erectile cluster (body, crura, and bulb) and the urethra. Pudendal neurovascular tissue is also shown. **B**, The clitoral (cavernous) nerves enter the clitoral body medially near the bifurcation.

COMPONENTS OF REDUCTION CLITOROPLASTY

General Concepts

Feminizing surgery deserves the same meticulous attention as masculinizing reconstructive procedures. Feminization is equally delicate despite its more deconstructive nature. Surgeons should understand the clitoral neurovascular anatomy and the wide spectrum of “normal” female genital anatomy before performing feminizing genitoplasty. Balancing cosmesis and functional outcomes is important; surgeons must keep in mind that resources are highly variable and may place limits on achieving a normal appearance. Optimizing the potential for intact sexual function is essential, but the patient or parents by proxy must understand that sexual function may be impaired because of nonanatomic or nonphysiologic factors. Multiple discussions regarding goals and reasonably expected short-term and long-term outcomes are critical. Sharing of medical information and psychological support are key elements of the work of surgeons and multidisciplinary teams.

Degloving

All adhesions between the glans clitoris and inner prepuce are bluntly lysed. A traction suture of 4-0 or 5-0 Ethibond is placed in the dorsal midline of the glans (Fig. 62-3). Early and late steps are taken to adequately conceal the clitoris and to fashion a cosmetically appropriate clitoral hood. The first of these steps is to choose a site for the degloving incision. Unlike penile procedures such as circumcision or hypospadias repair, in which the incision may be 6 to 8 mm from the glans margin, the initial incision for clitoroplasty should allow sufficient inner preputial tissue to cover the glans (Fig. 62-4). Although surgeons should recognize that the inner preputial tissue has properties suitable for the vestibular aspect of the labia minora, this tissue should be shared to create a clitoral hood that minimizes exposure while preventing entrapment of the glans. The outer prepuce and skin of the hypertrophied clitoris will ultimately be used to fashion the labia minora (see the section Labioplasty). The clitoral skin and clitoris itself are the most sensitive tissues in adults with normal clitoral anatomy¹⁰ and therefore should be fully preserved in reconstructive procedures.

Fig. 62-3 The traction suture dorsally allows exposure of all elements of dissection. Ventral curvature still results in some rotation of the clitoral body early in the dissection; additional manual retraction may be helpful for ventral dissection. The degree of virilization is variable; in this case, the fusion and rugation of the labia majora and location of the urogenital sinus proximal to the base of the hypertrophied clitoris are shown.

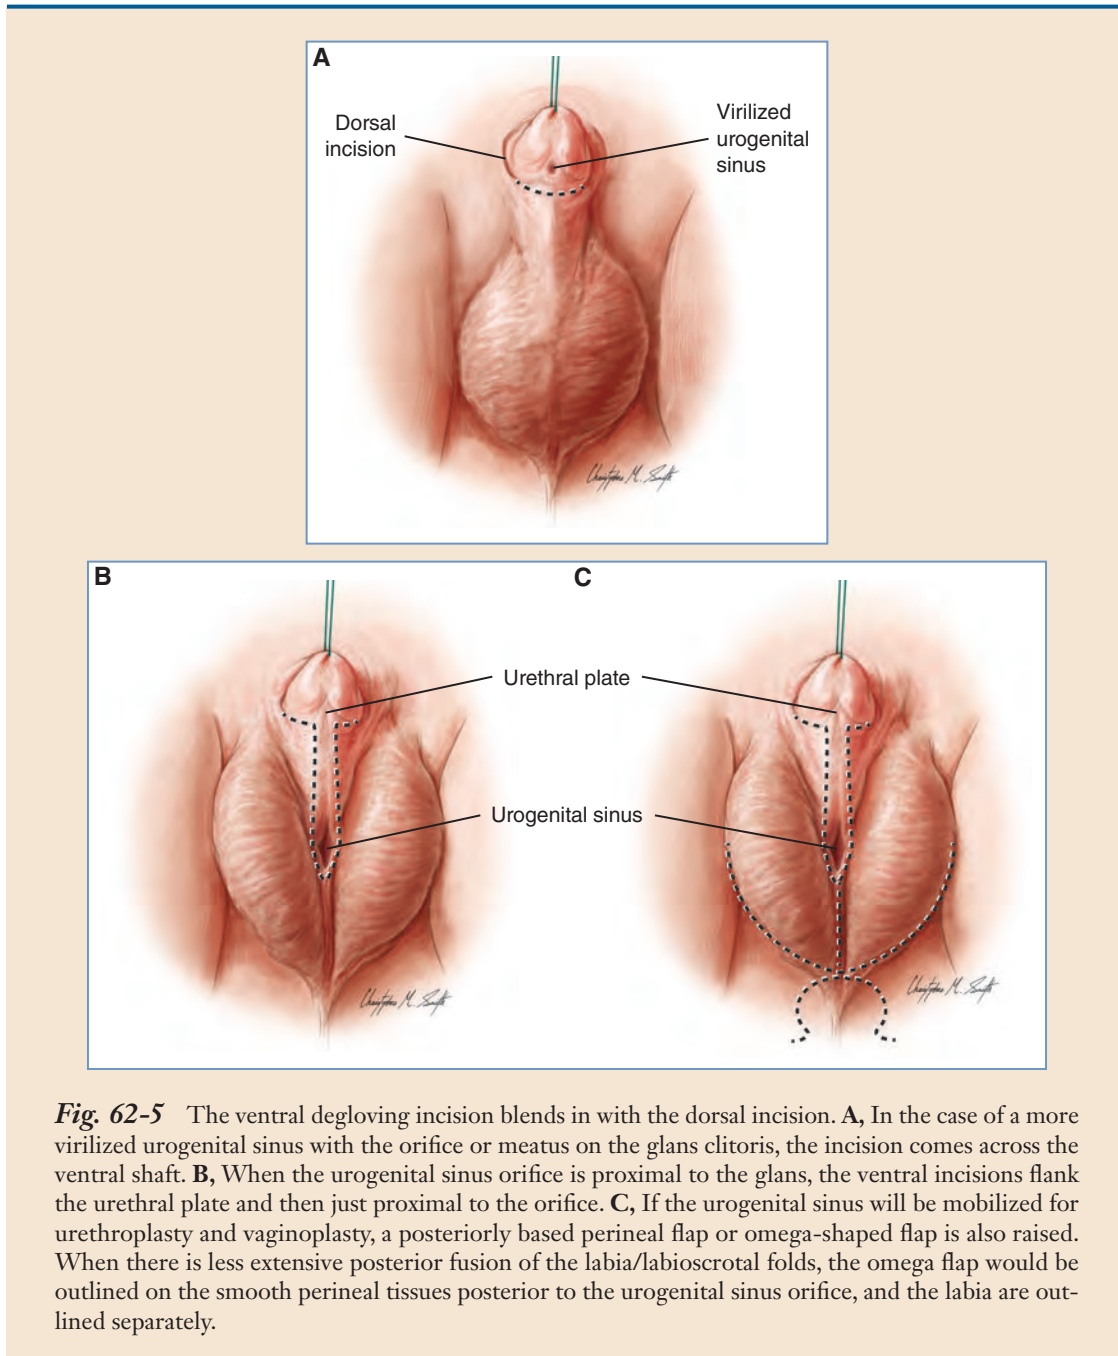

Fig. 62-4 The traction suture allows exposure dorsally for degloving. The clitoral preputial adhesions have been lysed, and the skin is retracted to expose the inner prepuce. The difference in character between the inner and outer prepuce is shown. The location of the degloving incision for the clitoroplasty as opposed to the standard incisions for circumcision or hypospadias in a male child is shown. The dorsal incision for clitoroplasty should allow adequate skin to cover the glans; this is the first step in constructing a clitoral hood.

The ventral incision comes across the shaft distally if the urethra is virilized with a glanular or coronal meatus, or it flanks the urethral plate in less virilized patients¹¹ (Fig. 62-5, *A* through *C*). If mobilization of the urogenital sinus for urethroplasty and vaginoplasty is also undertaken, the incision extends proximal to the urogenital sinus orifice. A posteriorly based perineal flap or omega-shaped flap is created to assist in dissection of the urogenital sinus. This flap is also reserved for incorporation into the spatulated posterior wall of the vagina to create a wider vaginal orifice and to reduce the risk of cicatrix formation. Certain approaches to vaginoplasty may not use this tissue, or the unique anatomy may not require the use of this flap. The pros of having this tissue available have been stated previously, but the drawback is that this tissue may be hair-bearing in the future and does not have mucosal properties typical of the vagina. Incisions are also created around the base of each labia majora to judiciously reduce the labia and to move them posteriorly to flank the new vaginal orifice.

The clitoris is sharply degloved to the base, dissecting the dartos with the skin, but leaving Buck's fascia and its underlying neurovascular tissue undisturbed. The clitoral length is often markedly increased by degloving and division of the urethral plate. The dorsal suspensory ligament should be left intact to support the glans in a natural position after reduction is complete.

Management of the Urethral Plate

After degloving the clitoris, the urethral plate with its underlying spongiosal tissue will be mobilized in preparation for work on the clitoral bodies. If the urethra is intact, it must be divided on the distal shaft and mobilized off the clitoral body before clitoral reduction.

Decisions will be made at this point based on the unique anatomy and the total surgical plan. If a urogenital sinus is present and a single-stage repair is elected, urethroplasty and vaginoplasty will be performed, along with feminizing genitoplasty. The urogenital sinus work will be performed after the initial clitoral preparation. The urethral plate will be divided distally and dissected off the clitoral body. Where it is divided may depend on the projected appropriation of the urethral plate and urogenital sinus tissue. Will the mobilized urogenital sinus be used for a portion of the vaginal wall, or will the sinus tissue be available for a mucosa-lined vestibule?^{11,12}

Will mobilization of the sinus for urethroplasty and vaginoplasty be deferred? In this case, the urethral plate is divided and partially resected to allow recession of the glans, while an adequate mucosal strip is maintained between the glans and the urethra⁶ (Fig. 62-6).

In patients with significant chordee and a short urethral plate in whom urogenital sinus mobilization will not be undertaken, the plate can be elevated and preserved without division. After the clitoral body tissues are reduced, the plate is returned to its natural location⁶ (Fig. 62-7). In addition to the natural mucosal strip separating the clitoris from the urethra, the intact plate may allow one additional source of perfusion for the glans.⁶

Fig. 62-6 The urethral plate is divided distally and then preserved in the child in whom clitoral reduction is performed but repair of the urogenital sinus is deferred. Note that the glans was reduced ventrally in this figure.

Fig. 62-7 When mobilization of the urogenital sinus will be deferred or is not required (based on a patient's unique anatomy and the surgical plan), the urethral plate may be elevated for clitoral body reduction without actually dividing the plate. The plate can be returned to its natural position without generating bulk or a bulge in this region only in patients with prominent chordee and a short plate.

Management of the Clitoral Body

Nerve-Sparing Clitoral Reduction Techniques

Several different nerve-sparing techniques are currently used, based on surgical training and preference. These approaches support the glans on an intact dorsal neurovascular pedicle while allowing debulking of the hypertrophied clitoral body.

In one approach, Buck's fascia and the neurovascular tissue are elevated as a unit off the dorsal aspect of the tunica albuginea. The glans remains attached to the neurovascular tissue but is dismembered from the two corporal bodies. Poppas et al¹³ have called this approach *nerve-sparing ventral clitoroplasty*. Buck's fascia is incised ventrally to minimize the risk of injury to the dorso-laterally fanning nerves. Dissection is carried out between the tunica albuginea and the neurovascular tissue circumferentially along the length of the clitoral body (Fig. 62-8, *A*).¹³ Papaverine is used to minimize spasm of the delicate vasculature. The erectile bodies are dissected, excised to within 1.5 to 2 cm of the bifurcation, and oversewn (Fig. 62-8, *B*).¹³ The glans is then seated onto the proximal corporal stump. The stump allows proximal engorgement and support of the glans. A vascular anastomosis is not performed. Great care is required to prevent kinking of the neurovascular tissue as the glans is reseeded.

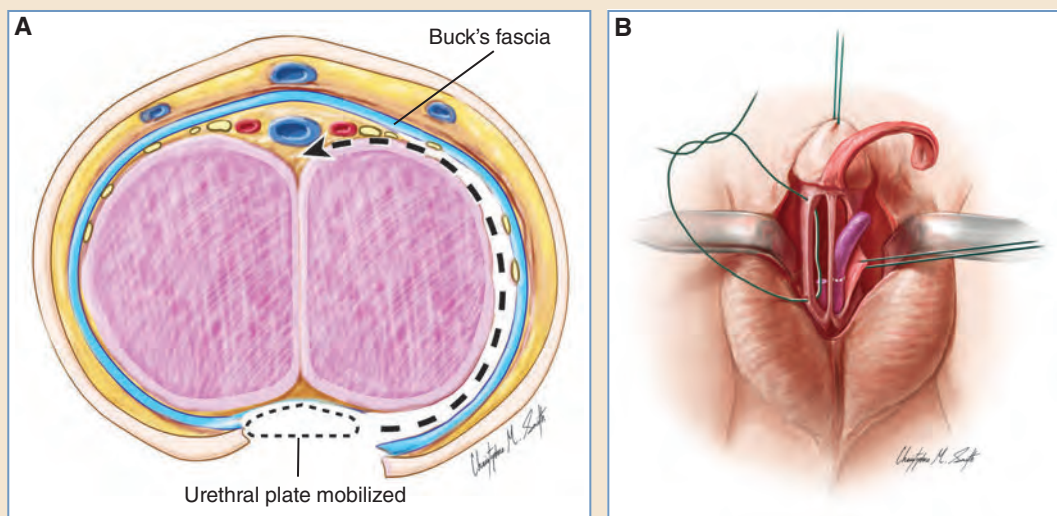

Fig. 62-8 Nerve-sparing ventral clitoroplasty. **A**, A cross-section of the clitoris. Buck's fascia is incised ventrally, and the dissection occurs between the tunica albuginea and the dorsal neurovascular tissues. Circumferential dissection along the clitoral body results in a sheath of neurovascular tissue and Buck's fascia. **B**, Glans and nerves have been elevated off the erectile bodies. Bodies are transected and excised proximally. The glans will be reseeded on the oversewn proximal tissue. The surgeon must avoid kinking of the neurovascular tissue.

Another often-endorsed nerve-sparing approach leaves the dorsal and lateral tunica albuginea intact; meanwhile, the neurovascular tissue maintains its natural position between Buck's fascia and the tunica albuginea (Fig. 62-9, *A*). Longitudinal incisions are created bilaterally through the tunica albuginea ventrally. The erectile tissue is dissected as a unit from inside the rind of the tunica albuginea with sharp and blunt dissection.⁶ The septum may be traversed and resected with the spongy erectile tissue of both sides, or each side may be dissected separately. The tissue is dissected from the distal tips of the clitoral bodies down to within 1 cm of the bifurcation. The spongy cavernosal tissue is ligated with absorbable suture and excised (Fig. 62-9, *B*),⁶ and the glans is seated on the corporal stump. I prefer this approach over nerve-sparing ventral clitoroplasty,¹³ because the risk of inadvertent neurovascular injury, despite meticulous technique, is theoretically reduced and the residual tissue is not notably bulky.

Because of the known neurovascular anatomy,⁸ dissection between the erectile bodies at the bifurcation or encircling the crura at the bifurcation to fashion a tourniquet is not recommended.

One additional contemporary option exists. This approach preserves all clitoral tissue until the child has reached the age of consent or well-informed assent and can choose formal reduction or even reconstruction to whole, as desired. Pippi Salle et al¹⁴ described a novel clitoroplasty technique in which the glans clitoris and dorsal neurovascular tissue are dissected as a unit off the clitoral body. The clitoral body is then split down the midline, and each erectile body is rotated and buried in its ipsilateral labium majus as the labial work is completed. It is not yet known whether engorgement of the repositioned but retained clitoral bodies will be pleasurable, painful, both, or neither.

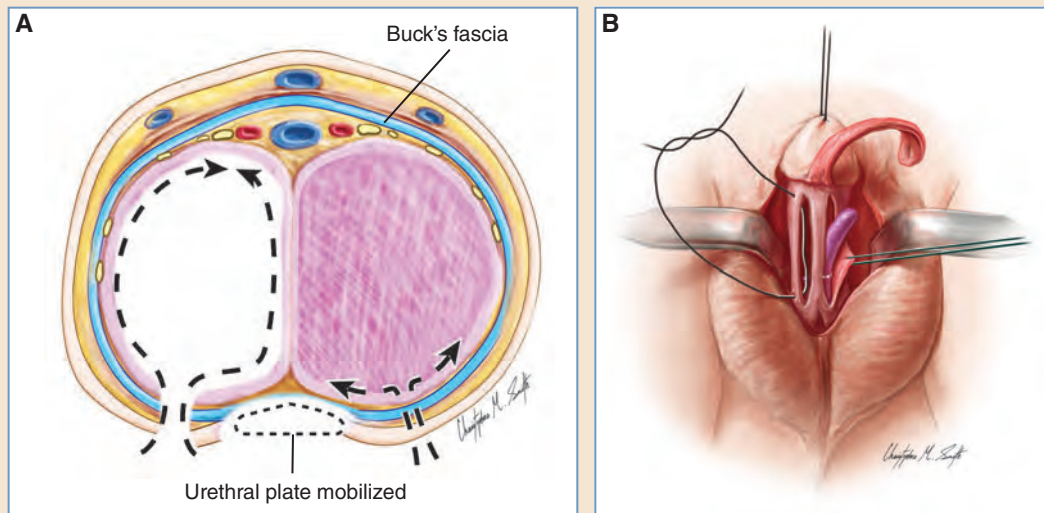

Fig. 62-9 Another common nerve-sparing approach for clitoral reduction. **A** and **B**, A ventral incision prevents injury to the nerves. An incision through the tunica albuginea facilitates removal of the spongy erectile tissue without resecting the tunica albuginea or dissecting near the neurovascular tissue.

Recession of the Glans and Creation of the Clitoral Hood

Reduction of girth or diameter of the glans is largely the surgeon's preference. In pediatric feminizing genitoplasty, I typically do not reduce the glans, because there is no clear evidence that a well-concealed but larger than typical glans is medically harmful or otherwise bothersome. Great caution has just been taken to preserve viability and sensation, and reduction of the glans *could* have an adverse impact, even if the surrounding tissue maintains sensation. Achieving a glans clitoris of entirely normal proportions is not feasible in patients having clitoral reduction. Focus is redirected from size to recession of the glans and concealment with a reconstructed hood and labia to achieve a feminine cosmetic result that minimizes overstimulation of the sensate, reconstructed glans clitoris. If reduction is necessary in a very large glans, a ventral wedge resection is least likely to affect nerves.

A clitoral hood is fashioned in two stages as the glans is recessed. The inner prepuce preserved at the time of the initial skin incision is brought up and over the glans and configured to a prepuce-lined hoodie shape (Fig. 62-10, *A* and *B*).

The glans is positioned next. If the dorsal tunica albuginea has been left intact, the glans is recessed and secured to the proximal clitoral bodies by suturing together the proximal and distal margins of the corporotomies. This is done more to provide support than hemostasis. The neurovascular tissue positions itself in the subcutaneous space at the dorsum of the clitoris, near the

Fig. 62-10 Creation of the inner layer of the clitoral hood. The collar of the inner prepuce is flipped over to cover the glans clitoris. **A**, A sagittal view shows the shape of the hood. **B**, The hood is not cinched around the glans but instead will be sutured to the distalmost aspect of the urethral plate after the glans is recessed. The dotted line shows the contour of the glans clitoris beneath the inner layer of the hood. The glans has not been reduced but is well concealed.

pubis (Fig. 62-11). A large glans may be inadequately supported on the base of the clitoral body. It may tip more unnaturally toward the urethra and appear more conspicuous with retraction of the labia, particularly if the mucosal strip (former urethral plate) between the urethra and vagina is left too short. In this case, supporting sutures may be effective in the dorsal midline of the dermal side of the preputial hood, but they must not injure, impinge on, or kink the neurovascular tissue.

The remaining prepuce and clitoral skin are split in the midline, thus creating Byars flaps (Fig. 62-12). The skin is split approximately 1.5 cm from the base and adjusted as needed for the unique anatomy and glans size. The intact skin becomes the outer layer of the clitoral hood. The dermis is judiciously plicated to create a subtle finlike contour for the clitoral hood. The surgeon's eye determines the appropriate extent of contouring (Fig. 62-13). The outer hood is sutured to the inner hood with interrupted, fine absorbable sutures.

Labiaplasty

Byars flaps, which are created from the sensate clitoral skin, become the labia minora. If no additional excess urogenital sinus tissue is available to line the vestibule, the medial edge of the Byars flap is sutured to the mucosal strip/urethral plate with interrupted absorbable sutures. Because the flaps are essentially rectangular and not representative of typical labia, judicious tapering and trimming distally will achieve the desired configuration. Similarly, a dog-ear of tissue is excised

Fig. 62-11 A sagittal view as the glans is seated on the proximal erectile bodies. The erectile tissue has been ligated for hemostasis, but the tunica albuginea remains intact. The position of the dorsal tunica albuginea, neurovascular tissue, and Buck's fascia is shown.

Fig. 62-12 Preparing the skin for the clitoral hood and labia minora. The remaining dorsal skin is split in the midline to create Byars flaps. The incision is stopped about 1.5 cm from the base to preserve intact skin for the outer layer of the clitoral hood.

Fig. 62-13 Finishing the clitoral hood and creating labia minora. **A**, The outer layer of the hood is contoured by placing several absorbable sutures on the underside to plicate the dermis (the *caret marks* are shown to signify contour). **B**, The inner and outer layers of the hood are joined. Byars flaps flank the urethral plate and urethra or urogenital sinus to become the labia minora.

Fig. 62-14 Tailoring the labia minora. The shape of the Byars flaps is not representative of the labia minora, but as the tissue is tucked down, it develops a finlike contour that is not well represented in the two-dimensional view. The outer corner is trimmed for a tapered contour, and a dog-ear of tissue is excised anteriorly to create a contour between the labia minora and labia majora.

anteriorly between the inner and outer labia to create a natural-appearing cleft (Fig. 62-14). A two-layer closure with dermal anchoring sutures and cutaneous sutures is recommended at the tips of the labia minora to minimize the risk of dehiscence.

Cosmetic work on the labia majora will depend on whether urogenital mobilization and vaginoplasty with or without a posteriorly based perineal flap were undertaken during the reconstruction. The labia majora are mobilized by a U-shaped incision with the underlying fibrovascular and lipomatous tissue and moved posteriorly to flank the vaginal introitus. If an omega flap was advanced and incorporated into the posterior vaginal wall, the labia majora advance posteriorly, lateral to the omega flap. Debulking for a smooth contour may be incorporated for more virilized, rugated labia, although rugation cannot be fully addressed surgically. If urethroplasty and vaginoplasty were deferred, typically in patients with lesser labial fusion, reconfiguration of the labia majora would also be deferred in most patients.

OUTCOMES

From surgeons' perspectives, cosmetic outcomes have been considered very good for decades. We are, however, obligated to seek means to objectify cosmetic outcomes and to assess satisfaction and sexual function, because findings from the most contemporary clitoral reduction techniques are not yet available. Limited early information suggests a favorable outcome. However, measures to assess cosmetic outcome, intact neurovascular function, and adequacy of sexual function are not well defined.^{13,15} Intact perfusion and sensation have been physically confirmed in the first few years after nerve-sparing ventral clitoroplasty, but longer-term testing is needed.¹⁶ Fully intact sensation to touch and vibration may not be the only factor in perception of normal sexual function,¹⁷ but others find a linear relationship between sensation and function.¹⁸ Older reports describe results from historical techniques or very heterogeneous groups and may or may not be relevant.^{15,19} Nonanatomic (hormonal or psychological) factors may also affect sexual function.²⁰ We do not understand the impact of deferring surgical decision-making until adolescent–young adult age. More than one study suggests that patients prefer surgery at a young age, but the individuals queried had surgery in childhood.^{20,21}

After reconstructive surgery is performed in infancy or early childhood, it takes time to reach an age for confidence regarding intact sexual function. Relatively uncommon diagnoses yield relatively uncommon procedures and develop into meaningful uniform series only after many years. More work is needed in objectively assessing outcomes with and without surgical intervention.

KEY POINTS

- Patients with disorders of sex development, or intersex conditions, should receive short-term and long-term guidance of a multidisciplinary team of specialists. Long-term psychological support for the patient and parent is essential.
- Surgical management, including all elements of feminizing genitoplasty, should only be undertaken after extensive counseling and only by surgeons with a strong grasp of the anatomy and experience with complex genital reconstruction.
- Current understanding of genital anatomy indicates that nerve-sparing approaches to clitoral reduction are the best choice to preserve clitoral function. Additional physical testing and validated patient-reported outcomes are needed to fully understand clitoral function and sexual function outcomes after feminizing genitoplasty.
- Appropriation of tissue resources must be considered, whether a single-stage procedure with feminizing genitoplasty and management of the urogenital sinus/vaginoplasty is planned, or whether the latter portion will be deferred until maturation.

Phalloplasty

Richard J. Redett • Sami H. Tuffaha

Without proper treatment, a male child with penile absence, deficiency, or deformity can undergo debilitating functional and psychosocial sequelae. Beyond the obvious impact on urinary and sexual functioning, a significant penile defect can damage a boy's developing sense of identity and self-esteem, with profound and long-lasting effects on global well-being and interpersonal relationships. Reconstructive surgery can have a strong, positive impact when integrated into a holistic team approach that addresses the urologic, sexual, and psychological pathologies associated with genital defects.

CONGENITAL ANOMALIES

Penile defects requiring surgical reconstruction can result from trauma, neoplasm, and vascular disease; however, congenital anomalies are the most common cause in pediatric patients.¹ The congenital anomalies most likely to warrant phalloplastic reconstruction include micropenis, aphallia, ambiguous genitalia, epispadias, and bladder and cloacal exstrophy (Table 63-1).

Each of these malformations is associated with a unique set of genital, urologic, and pelvic anatomic defects and physiologic abnormalities that must be treated. Knowledge of how each of these malformations affects normal anatomy and sexual and urologic function will facilitate surgical decision-making and patient counseling and will maximize the likelihood of positive outcomes.

Table 63-1 Common Penile Congenital Anomalies

Condition	Incidence	Definition	Etiologic Factors
Aphallia	1 in 10,000,000	Agenesis of the penis	Failure in embryologic development of the cloacal folds to generate genital tubercles
Micropenis	1 in 200	Proper proportions and development but <2.5 standard deviations below the appropriate size for age	Defect in the hypothalamic-pituitary-gonadal axis
Ambiguous genitalia	1 in 4200	Also known as <i>disorder of sex development</i> (DSD) A spectrum of disorders leading to questionable or ambiguous genital appearance at birth	Congenital adrenal hyperplasia Leydig cell failure Testosterone biosynthesis enzyme defects Androgen insensitivity syndrome Congenital anorchia Gonadal dysgenesis Klinefelter syndrome (47,XXY)
Hypospadias	1 in 250	Urethral malformation, early termination and opening on the ventral penis	Undervirilation, decreased testosterone or dihydrotestosterone, elevated antimüllerian hormone
Epispadias	1 in 120,000	Urethral malformation, early termination and opening on the dorsum of the penis	Failure of mesodermal migration with premature rupture of the cloacal membrane Failure of midline fusion of the genital tubercles
Bladder exstrophy	1 in 10,000 to 1 in 50,000	Abdominal wall defect, pelvic diastasis, penile defect, epispadias, bladder open and exposed	Failure of mesodermal migration with premature rupture of cloacal membrane Failure of midline abdominal wall fusion after separation of genitourinary and gastrointestinal tract
Cloacal exstrophy	1 in 200,000 to 1 in 400,000	Abdominal wall defect with extrusion of the hindgut and cecum and splitting of the bladder, penis, and scrotum	Failure of mesodermal migration with premature rupture of the cloacal membrane Failure of midline abdominal wall fusion before separation of the genitourinary and gastrointestinal tracts

A cursory understanding of genital embryogenesis is helpful in understanding the development of congenital genital anomalies. The human fetus is sexually undifferentiated at 8 weeks' gestation and has both wolffian (male) and müllerian (female) genital ducts. From 12 to 16 weeks' gestation, sexual differentiation occurs. The developing testes secrete antimüllerian hormone, resulting in regression of the müllerian ducts. Androgens released from the testes maintain the wolffian ducts, which give rise to the internal genitalia and allow differentiation of the external genitalia; this process involves enlargement of the genital tubercle into the glans, fusion of the urethral/genital folds to form the shaft, and midline fusion of the genital swellings to form the scrotum. Derangements in this process can lead to congenital anomalies of the genitalia.

Aphallia is a rare condition in which the penis fails to develop in utero, resulting in complete absence of the penis. Many of these patients have associated genitourinary anomalies that need to be addressed. Historically, these patients underwent gender reassignment surgery, including orchiectomy, at a young age. However, this practice has largely fallen out of favor, because evidence suggests that many of these patients will maintain a male identity.² Many are good candidates for phalloplasty.

The word *micropenis*, or *microphallus*, refers to a normally formed penis that is shortened more than 2.5 standard deviations below the age-adjusted mean. The cause of micropenis is often endocrinologic in nature, with insufficient androgen stimulation in utero. Patients with hypogo-

nadotropic hypogonadism have hypothalamic dysfunction resulting in insufficient gonadotropin-releasing hormone (GnRH) production, whereas those with hypergonadotropic hypogonadism have inadequate androgen release in response to a normal GnRH stimulus. The first-line treatment for micropenis is testosterone, either systemically or topically. However, in severe cases that do not respond to medical management, surgical lengthening and skin grafting of the penis or phalloplasty can be considered at a later age (Fig. 63-1).

The term *ambiguous genitalia* describes a broad set of congenital defects in which the external genitalia have both male and female characteristics. Micropenis is often grouped into this category. Ambiguous genitalia can develop in males and females; however, typically only genetic males with ambiguous genitalia are considered candidates for phalloplasty. Ambiguous genitalia in genetic males can have an array of features, including a small penis resembling a clitoris, a urethral opening above or below the penis, an undifferentiated scrotum resembling labia, and undescended testes. The specific surgical approach to ambiguous genitalia depends on which features are present (Fig. 63-2).

Hypospadias is a commonly occurring congenital penile defect in which the urethral meatus is proximal and ventral to its normal location in the distal glans. It is the result of partial or complete failure of the urethral folds to fuse, causing disruption of distal urethral formation.

Fig. 63-1 Two adolescent males with micropenis.

Fig. 63-2 This genetic male with ambiguous genitalia had early gender reassignment. He was raised as a female but later underwent gender reconversion to a male in adolescence.

Fig. 63-3 Exstrophy-epispadias complex. **A**, This 6-month-old boy has epispadias. **B**, This 8-month-old boy has bladder exstrophy. **C**, This 12-month-old boy has cloacal exstrophy.

Epispadias, bladder exstrophy, and cloacal exstrophy are thought to belong to a spectrum of genital malformations called an *exstrophy-epispadias complex* (EEC).³ Bladder exstrophy presents with a lower abdominal wall defect and severe pubic symphysis diastasis, with exposure of an open bladder and urethra and dorsal urethral opening. Cloacal exstrophy is more severe, with a bilobed bladder separated by the cecum. Epispadias, the mildest form of EEC, presents with a closed bladder, a dorsally open urethral meatus, and mild pubic diastasis. These defects result from failure of mesodermal migration into the cloacal membrane that separates the ectoderm and endoderm of the anterior abdominal wall. This presumably results in premature rupture of the cloacal membrane. The timing and location of rupture determine whether a patient will develop epispadias, bladder exstrophy, or cloacal exstrophy.⁴

The genital defects associated with EEC can present a difficult reconstructive challenge. Management often involves staged reconstruction of the bladder, urethra, abdominal wall, and genitalia and requires close coordination and cooperation between the reconstructive surgeon and the urologist. The genital defects associated with EEC vary in severity. In isolated epispadias, the urethral meatus is located on the dorsal surface of the penis at the penopubic angle, and the glans is open dorsally. The phallus is typically shortened with dorsal chordee. Epispadias can sometimes be managed with standard lengthening procedures; however, phalloplasty can achieve favorable results in severe cases. In cases of exstrophy, the penis can be halved and separated from the midline. In such cases of severe deformity, phalloplasty is indicated^{5,6} (Fig. 63-3).

GENDER DYSPHORIA

Pediatric phalloplasty is typically performed to reconstruct anatomic penile defects only; however, reconstructive surgeons may see patients seeking gender reassignment. *Gender dysphoria* describes a marked difference between a person's expressed/experienced gender and the gender perceived by others. According to the Diagnostic and Statistical Manual of Mental Disorders (DSM-5),⁷ the condition must be present and stable for at least 6 months to be diagnosed. Gender dysphoria can manifest in many ways. For example, a patient can have strong feelings and reactions typical of the other gender and strong desires to be treated as the other gender and/or to change his or her own anatomic characteristics to those of the other gender. For patients suspected of having gender dysphoria, referral to appropriate specialists for multimodal therapy is critical.

A recent report by the American Psychiatric Association Task Force on Treatment of Gender Identity Disorder⁸ provided evidence-based treatment recommendations for patients with gender dysphoria. For children younger than 12 years of age diagnosed with gender dysphoria, psychoeducation and counseling to optimize psychological adjustment and well-being are the mainstays of treatment. Without treatment, most of these children will eventually become comfortable with their natal gender, and some will identify as transgender or transsexual in adulthood.⁹

In adolescents with persistent cross-gender identity and behavior, gender dysphoria often worsens with the onset of puberty. In addition to psychotherapy, education, and counseling, these patients may be appropriate candidates for hormonal therapy with gonadotropin-releasing hormone to suspend puberty. Before hormonal therapy is considered, coexisting psychological conditions that may contribute to dysphoria and confound an accurate diagnosis need to be identified and treated. In the United States, gender reassignment surgery is rarely, if ever, performed for patients younger than 18 years of age.

NONOPERATIVE AND OPERATIVE TREATMENT OPTIONS

Congenital penile deficiency resulting from fetal testosterone deficiency may respond to testosterone treatment delivered systemically and/or locally. A response to testosterone treatment can be seen in infancy, later in childhood, and in adolescence. Testosterone is the first-line treatment for patients with congenital hypogonadic micropenis. If medical treatment is unsuccessful, penile lengthening or phalloplasty can be considered.

Currently, congenital micropenis resulting from fetal testosterone deficiency is the only congenital penile defect that has a medical treatment. All others are treated with surgical intervention. Milder genital defects are sometimes amenable to primary repair, local tissue rearrangement, and/or lengthening procedures. Some defects are amenable to local flap reconstruction, but the surrounding tissue has been scarred by multiple previous operations. In these cases, tissue expansion has shown great utility.¹⁰ Tissue expansion is also useful in conjunction with lengthening procedures (Fig. 63-4). Tissue expansion can also be used to create a neourethra with capsular flags in the setting of hypospadias repair⁹ (Fig. 63-5). However, when a

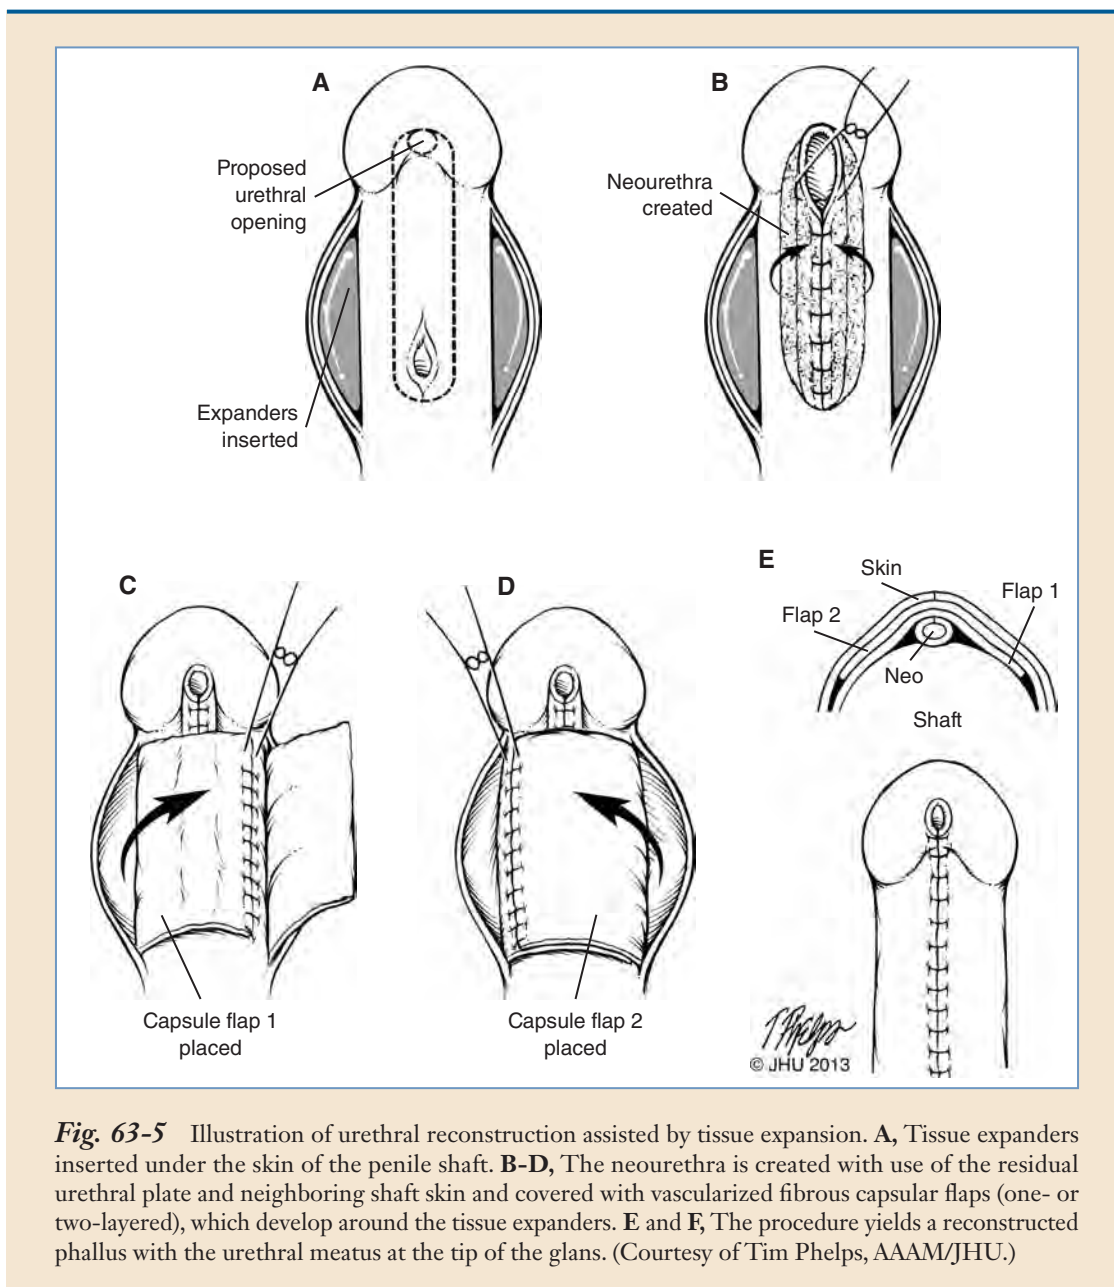

Fig. 63-4 A, Micropenis. B, Tissue expanders are inserted under the shaft skin bilaterally. C and D, When the tissue expander is removed, the underlying structures are lengthened, and the shaft is resurfaced with redundant skin.

satisfactory result cannot be achieved, phalloplasty with pedicled locoregional flaps or free tissue transfer should be considered.

In the past, aphallia and severe congenital penile defects were treated with gender reassignment, with bilateral orchiectomy, penectomy (when a penis was present), labioplasty, clitoroplasty, and vaginoplasty. This practice is no longer popular, because patients typically maintain a male identity after surgery, and effective techniques for phallopastic reconstruction have emerged¹¹ (see Fig. 63-2).

Options for Phalloplasty

The goals of phalloplastic reconstruction include the formation of an aesthetically acceptable neophallus; a competent urethra that allows voiding while standing, in patients without continent urinary stomas; enough stiffness for sexual penetration; erogenous and protective sensation; and minimal donor-site morbidity. Over the past century, the surgical approach to total phalloplasty has evolved significantly. Numerous approaches have emerged, each providing some, but not all, of the ideal characteristics of a neophallus. The earliest techniques used pedicled flaps from the abdomen and groin. More recently, with the advent of microsurgical technique, a number of options involving free tissue transfer have gained popularity. Because they typically provide better function, sensation, and aesthetic outcomes, free flaps have largely replaced pedicled options for phalloplasty.

Pedicled Abdominal Flap

In 1936 Bogoras¹² described the first total penile reconstruction, which he called “penis plastica totalis.” He used a random-pattern, pedicled flap from the abdomen and reported sexual function. Taylor et al¹³ and Davies and Matti¹⁴ in 1988 described a single-stage approach to a pedicled rectus abdominis myocutaneous flap supplied by the deep inferior epigastric vessels. The flap was tubularized, and an implant was inserted, facilitating sexual function. Although the flap is a reasonable option when microsurgery is not possible, it is insensate, and the aesthetics are often suboptimal.

Pedicled Groin Flap

Smith et al¹⁵ first described the pedicled groin flap for phalloplasty in 1972. It is an axial flap based on the superficial circumflex iliac vessels and performed in a single-stage reconstruction, with or without an implantable device to provide stiffness. In 1990 Sun et al¹⁶ reported on a modification of the groin flap that incorporated a portion of the iliac crest to allow penetration. Although a groin flap is an option for phalloplasty, it is limited by poor sensation and aesthetics, similar to a pedicled abdominal flap. Furthermore, groin flaps often result in a small neophallus, because the donor tissue is limited. For these reasons, the groin flap for phalloplasty has largely been replaced by free flap options.

Radial Forearm Free Flap

Ever since Song¹⁷ described the radial forearm free (RFF) flap in 1982, its popularity has grown, and many consider it to be the benchmark for phalloplasty.¹⁸ RFF flaps are well suited for creating a neophallus, in part because it is relatively thin, supple, and hairless, thus mimicking native penile shaft skin. With additional modifications to define the penile subunits, the flap provides much-improved aesthetic outcomes (Fig. 63-6). Furthermore, because it receives robust sensory innervation from both the medial and lateral antebrachial cutaneous nerves, an RFF flap, when neurotized, can provide more than adequate erogenous and protective sensation, and patients often report the ability to orgasm.⁶ To achieve rigidity, an implant is often inserted in a second stage. However, the placement of an implant introduces a significant risk of extrusion.^{6,18} An alternative approach to provide rigidity without an implant involves harvesting a portion of the radius within the flap; however, this approach is limited by the nuisance of permanent rigidity and a high rate of bone resorption. RFF flaps are prone to high rates of urinary fistula and stricture and a conspicuous donor site that carries the stigma of gender reassignment in transsexual patients.^{19,20}

Fig. 63-6 A, An RFF flap without glanuloplasty and coronaplasty modifications. B, An RFF flap with glanuloplasty and coronaplasty modifications, resulting in improved aesthetics and a more realistic appearance of the neophallus.

Anterolateral Thigh Flap

Felici and Felici²¹ first introduced the anterolateral thigh (ALT) flap for phalloplasty in 2006. The flap is raised as a fasciocutaneous perforator flap based on the descending branch of the lateral circumflex femoral vessels and can be used as a free pedicled flap for phalloplasty. This flap has several theoretical advantages over an RFF flap, including a less conspicuous donor site, skin that is potentially less pigmented, and greater soft tissue bulk.²² However, the skin of an ALT flap is often much thicker and less supple than that of an RFF flap; therefore it may be less aesthetically pleasing. Similar to RFF flaps, ALT flaps can be neurotized for sensation using the lateral femoral cutaneous nerve of the thigh; however, it appears to provide significantly less erogenous sensation than that of RFF flaps.²³

Latissimus Dorsi Myocutaneous Free Flap

The latissimus dorsi myocutaneous free flap was first used for phalloplasty in 1996.²⁴ Based on the thoracodorsal vessels, this flap is a reliable option for phalloplasty that provides considerable soft tissue bulk. More recently, modifications to the flap for neurotization have been described. Perovic et al²⁵ reported that approximating the thoracodorsal nerve of the flap to the ilioinguinal nerve result in return of some protective sensation. However, the mechanism by which this occurs is unclear, given that a sensory nerve regenerates into a motor pathway. Even with neurotization, erogenous sensation and orgasm have not been achieved with the use of latissimus dorsi myocutaneous free flaps. Ranno et al²⁶ approximated the thoracodorsal nerve of the flap to the nerve of the gracilis and reported that patients were able to voluntarily contract the latissimus muscle within the flap to achieve penetration without an implant.

Fibular Osteocutaneous Free Flap

To overcome the lack of intrinsic rigidity of the RFF flap and the resulting need for an implant, Sadove et al²⁷ in 1993 reported using a fibular osteocutaneous free flap for phalloplasty. The flap is perfused with the peroneal vessels, and the lateral sural cutaneous nerve can be used to provide sensory neurotization, although the sensibility of the flap is poor compared with that of an RFF

flap. The primary advantage of fibular osteocutaneous free flaps is inclusion of a long portion of the fibula to facilitate penetration without an implant. Despite the value of intrinsic rigidity provided by this flap, a permanently erect neophallus can be difficult to conceal and uncomfortable. Furthermore, the bony component within the flap is highly susceptible to resorption and warping.

PREOPERATIVE ASSESSMENT AND PLANNING

The preoperative assessment of a patient with a congenital penile defect begins with a careful physical examination and discussion with the referring urologist to determine the extent of the defect. During the initial evaluation, surgeons should consider whether a reasonable result can be achieved with lengthening procedures and local flaps or skin grafts or whether neophallus reconstruction is required to provide an acceptable outcome. The components of the native penis that can be incorporated into a neophallus are identified. If a functional glans is present, it can be incorporated into the ventral base of the neophallus to augment erogenous sensation. When the corpora are present and salvageable, they can also be incorporated to provide some soft tissue bulk and stiffness within the flap and to help seat an erectile implant. However, in cases of aphallia or severely deformed genitalia, incorporating native components may not be an option.

The length and patency of the urethra and the status of the more proximal urinary system are important preoperative considerations. The goal is to allow urination through the neophallus when possible. However, many children with bladder or cloacal exstrophy undergo bladder neck transection and creation of an umbilical continent urinary stoma. The native urethra is brought out through the ventral base of the neophallus to allow ejaculation, but patients will continue to catheterize the umbilical urinary stoma after reconstruction.

Surgeons need to determine whether associated deficits and comorbidities will preclude or minimize the usefulness of phalloplastic reconstruction. The reconstruction options are carefully explained to the patient's caregivers. Older children and teenagers are included in these conversations and play a central role in decision-making. Setting realistic expectations for patients and families is critically important.

After a decision is made to proceed with phalloplasty, the various donor-site options are thoroughly discussed with the patient and family. The potential donor sites are examined to assess appropriateness for use. For example, patients with excessive subcutaneous adiposity may not be ideal candidates for trunk- and thigh-based flaps. Previous surgical scars are another reason to avoid a particular donor site. Before proceeding with an RFF flap, an Allen test and Doppler ultrasound of each extremity are always performed to ensure adequate circulation to the hand through the ulnar artery. If these tests are equivocal, angiography may be performed.

When deciding on the optimal timing for phalloplasty, surgeons should consider the potential for neophallic growth and whether the penile construct will contain somatic and/or androgen-sensitive tissue components. A patient's native penis will grow exponentially during puberty in response to androgen surges. However, a neophallus constructed from somatic tissue will undergo much more modest growth. Therefore a patient's donor site must be large enough to construct a neophallus of nearly adult proportions. There are psychological advantages to performing phalloplasty in younger, prepubescent patients. For many surgeons, total penile reconstruction is best performed in patients 10 to 14 years of age. Surgery at this time minimizes the psychosocial distress that results from penile deformity and allows patients to adapt to the neophallus at a younger age. The growth patterns and psychological maturity of each patient needs to be considered when selecting the optimal timing for reconstruction. We have found that the likelihood of success is maximized when reconstruction is delayed until patients can fully cooperate with surgery and postoperative care. Most patients are able to do this after entering puberty.

SURGICAL APPROACH TO THE RADIAL FOREARM FREE FLAP FOR PHALLOPLASTY

Given the superior aesthetics and sensibility provided by RFF flaps, many consider it to be the benchmark for phalloplasty, and it is the senior author's (R.J.R.) preferred option. The surgical approach for an RFF flap will be described in detail, but many of the technical aspects and general considerations are applicable to the other approaches for phalloplasty (Figs. 63-7 through 63-10).

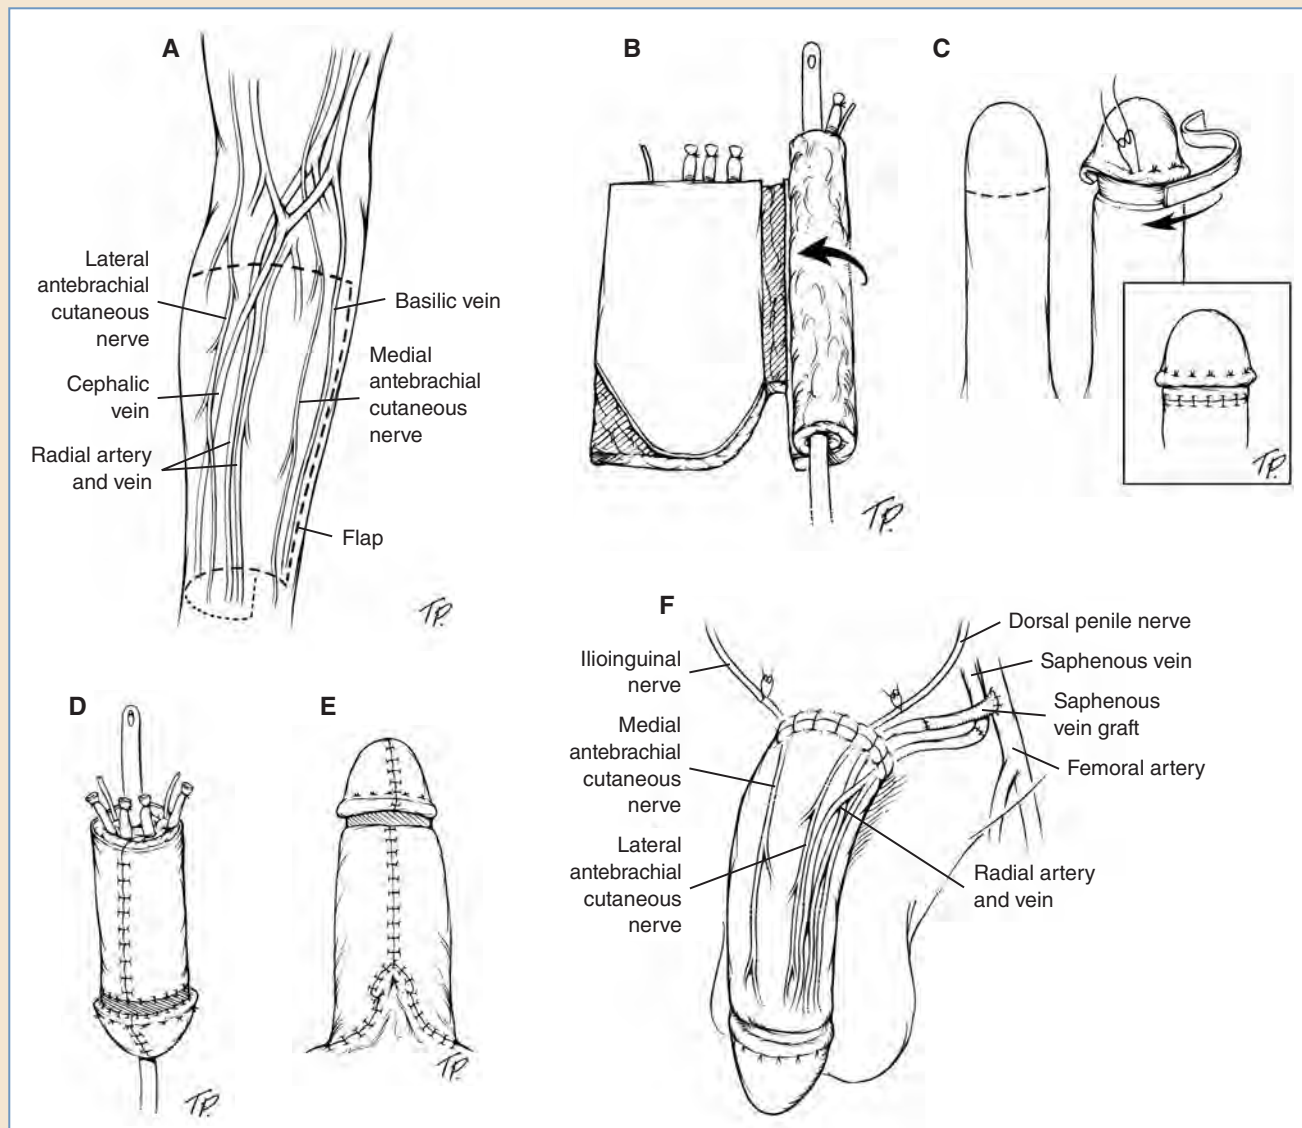

Fig. 63-7 The key steps of RFF flap phalloplasty. **A**, The flap is outlined, with important neurovascular structures to be included. **B**, The flap is rolled from ulnar to radial. An ulnar skin flap is rolled over itself to create a neourethra. The central, deepithelialized skin is buried in the flap. The flap is then rolled under itself to externalize the radial skin. **C**, Glanuloplasty and coronoplasty. The skin flap is folded inward and sutured to itself to create a glans. A full-thickness skin graft is applied to the donor site of the glans flap to create the appearance of a circumcision scar at the corona. **D**, The complete, prelaminated flap before transfer. **E**, The native glans is inset into the ventral base of the neophallus. **F**, The transferred flap, showing the vascular anastomoses and nerve coaptations. (Courtesy of Tim Phelps, AAAM/JHU.)

Fig. 63-10 A, This male patient had severe cloacal exstrophy and ambiguous genitalia. B, He is shown after reconstruction with an RFF flap phalloplasty.

Preparation and Harvest

The patient is placed in a supine position with the upper extremity from which the flap will be harvested abducted and supinated. A sterile upper extremity tourniquet is used during flap harvest for hemostasis. The flap is marked with dimensions of 14 by 14 cm. This typically includes the entire width and up to three fourths of the length of the volar forearm, beginning distally at the proximal wrist crease. Before the flap is elevated, the neoglans is defined by raising a transverse split-thickness skin flap across the distal forearm and rolling it under itself, where it is secured with resorbable sutures. The donor site of the glans flap is later covered with a full-thickness skin graft to better define the corona and to give the penis the appearance of having a circumcision scar. A coronal glans flap can also be created once the neophallus is tubed, but we think it is easier to do so before the flap is harvested. For patients who require a neourethra, a central longitudinal strip of skin is deepithelialized, separating the ulnar-sided skin panel (which will line the neourethra) and the radial-sided skin panel (which will provide the external skin of the neophallus).

The RFF flap is then raised in a standard fashion from distal to proximal. The radial artery and venae comitantes are identified between the flexor carpi radialis and the brachioradialis at the wrist and ligated. These vessels are elevated with the flap from the underlying tendons, while preserving the paratenon. We include the palmaris longus tendon, which is used to anchor the neophallus to the pubic bone. The medial and lateral antebrachial cutaneous nerves and the cephalic vein are identified and harvested with the flap. The flap is tubularized on the forearm before the pedicle is transected. From ulnar to radial, the flap is first rolled over itself to form the neourethra with the ulnar-sided skin panel and then under itself to externalize the radial-sided skin panel. The deepithelialized central panel is buried within the flap.

Recipient Site Preparation and Flap Inset

If two surgical teams are available, the recipient site and flap can be prepared simultaneously. A pediatric urologist is typically present to assist with recipient site preparation.

If the native penis is to be incorporated into the neophallus, the shaft skin is removed, and internal structures, including the urethra and the penile nerves, are isolated. When a competent urethra in continuity with the proximal urinary tract is present, the corpus spongiosum is severed from the glans so that it can be anastomosed to the neourethra within the flap. When the bladder neck has previously been transected, and the patient voids from an umbilical stoma, the urethra is left in continuity with the glans, and the external meatus is externalized through the ventral base of the neophallus to allow ejaculation. In either case, the glans is incorporated into the neophallus. It is first deepithelialized and then buried into the base of the neophallus, either during the phalloplasty or at a later stage to preserve a lifeboat in case of flap failure.

The dorsal penile nerves are isolated for erogenous sensation, and either the ilioinguinal or iliohypogastric nerve is isolated for protective sensation. These are approximated to the medial antebrachial cutaneous and lateral antebrachial cutaneous nerves. A number of recipient site vessels can be anastomosed to the radial artery to perfuse the flap, including the superficial circumflex iliac, the inferior epigastric, and the external pudendal and femoral arteries. The accompanying veins and the great saphenous vein can be used to provide venous outflow through the venae comitantes of the radial artery and the cephalic vein. We perform as many venous anastomoses as possible to reduce postoperative swelling and venous congestion.

The neourethra within the flap is anastomosed to the native urethra over a 10 or 12 Fr urinary catheter at the phalloplasty procedure. This is the senior author's preferred method for neourethra construction. Alternative approaches include prelaminating the flap with a full-thickness skin graft and inserting a tubed skin or buccal mucosa graft at a later stage.

Penile Prosthetic Implant

A penile prosthetic implant is inserted at a later stage and is typically delayed until late adolescence or early adulthood to minimize implant-associated risks, including soft tissue erosion, infection, and extrusion. Before an implant is inserted, protective sensation should be present and the patient should have a high level of maturity. We wait a minimum of 1 year after phalloplasty before inserting an implant to ensure the return of protective sensation before the procedure.

OUTCOMES AND LIMITATIONS

Many surgical options are available for phalloplasty, but none provides all of the qualities that a neophallus should have, including entirely acceptable aesthetics, a competent urethra with low risk of fistula and stricture, tactile and erogenous sensibility, enough stiffness and durability to allow sexual penetration, and minimal donor-site morbidity. An RFF flap is the most popular option for phalloplasty, because it provides excellent aesthetics and consistent erogenous and protective sensation. However, as with all methods of phalloplasty, the flap has significant limitations that require serious consideration. All of our patients who underwent RFF flap phalloplasty reported the ability to achieve orgasm and satisfaction with the neophallus appearance. Roughly half of our patients have had significant complications involving urinary strictures and fistulas and/or implant-associated complications requiring implant explantation; these findings are consistent with other large series.^{6,18}

FUTURE TREATMENT MODALITIES

Promising potential alternatives on the horizon may address the limitations of autologous phalloplastic reconstruction. For select patients in whom traditional reconstruction was unsuccessful and those without usable donor sites, a penile transplantation may offer a solution. For these difficult cases, the benefit provided by penile transplantation may outweigh the risks associated with immunosuppression. Careful screening, informed consent, and psychological evaluation will be of utmost importance in selecting appropriate patients, and the pool of eligible recipients will be limited and exclude the pediatric population. However, if and when tolerance protocols are developed that obviate the need for lifelong immunosuppression, penile transplantation may supplant traditional reconstruction, given the potential for markedly improved functional and aesthetic outcomes without donor-site morbidity.

Before penile transplantation can be successfully implemented, a number of technical considerations need to be addressed. We recently performed cadaveric perfusion studies to determine the optimal approach to vascularizing penile allografts. Because of the complexity of penile vascular anatomy, a number of vascular pedicles will have to be included to optimally perfuse the many crucial components of a penile allograft. Although the dominant blood supply to the penis is provided by the dorsal arteries, anastomosing the cavernosal arteries will probably augment corporal inflow necessary for engorgement and erection. For proximal levels of transplantation, blood supply from the external pudendal system may be important to prevent skin necrosis^{28,29} (Fig. 63-11 and Table 63-2).

Perhaps farther on the horizon, regenerative medicine may provide an ideal solution for penile reconstruction. Recent successes have been made in implanting tissue-engineered subunits of the genitourinary tract in animals and humans.³⁰ However, the complexity of penile anatomy presents many hurdles to overcome before a complete, functional penis can be grown in a laboratory.

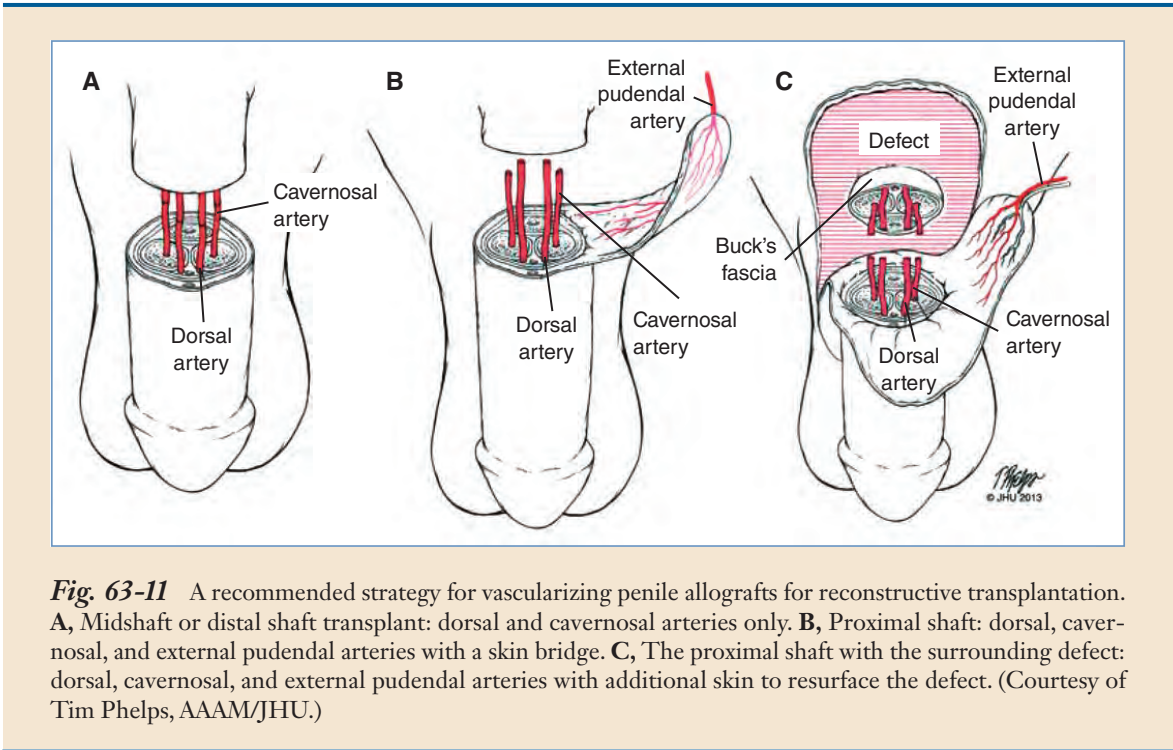

Table 63-2 Perfusion Territories		
Artery	Principle Perfusion Territory	
Dorsal	Glans and corpus spongiosum	
Cavernosal	Corpus cavernosum

KEY POINTS

- Congenital anomalies are the most common cause of penile defects requiring reconstruction in pediatric patients.
- Genetic males with aphallia or ambiguous genitalia should be considered for phalloplasty; early gender reassignment surgery for these patients has fallen out of favor, because many patients maintain their male identity.
- Congenital penile anomalies resulting from fetal testosterone deficiency may respond to testosterone therapy.
- *Gender dysphoria* is a term describing a marked difference between a person's expressed/experienced gender and the gender others would assign to him or her.
- Gender reassignment surgery is typically not performed before patients are 18 years of age.
- Some penile defects can be corrected with tissue expansion, local tissue rearrangement, and lengthening procedures.
- The goals of phalloplasty include the formation of an aesthetically acceptable neophallus; a competent urethra for voiding while standing, in patients without a continent urinary stoma; enough stiffness to allow sexual penetration; erogenous and protective sensation; and minimal donor-site morbidity.
- We consider the radial forearm free flap to be the benchmark for phalloplasty, because it provides superior aesthetics and sensation.
- Tissue engineering and vascularized composite allotransplantation may offer improved results in the future.

Anastomosing the cavernosal arteries may augment corporal inflow, which is necessary for erection. Although the dorsal arteries are critical for distal penile skin perfusion, the external pudendal artery should be used in proximal transplantation to ensure adequate shaft skin perfusion. Each of these arteries has a distinct and seemingly important perfusion territory that should be considered in a penile transplantation.

Pressure Sores and Neural Tube Disorders in Children

Michael S. Gart • Gregory A. Dumanian • Russell R. Reid

In the mid-1800s, Brown-Séquard¹ proposed pressure as the cause of bedsores in paraplegic patients. Since then, pressure sores have posed a significant challenge to the medical community. Plastic surgeons often lead the multidisciplinary team management of these wounds. Although both adult and pediatric patients develop these wounds, the underlying causes and comorbidities, treatments, and treatment success are significantly different. Adult patients have high recurrence rates of up to 80%,²⁻⁶ whereas pediatric patients have recurrence rates as low as 5%.⁷ This chapter focuses on the epidemiology, etiologic factors, conservative and operative management, and outcomes of pediatric pressure sores. Relevant data from our institution are presented to support the potential long-term success of operative repair in pediatric patients.

EPIDEMIOLOGY

Despite increasing awareness of the economic and medical consequences of pressure sores,⁸ their development is a persistent, common, and formidable challenge for health care institutions. In the United States, the incidence of this disease entity approaches 40% in some hospitals, 25% in long-term nursing facilities, and 20% in home care settings.⁹ The average cost to heal a single pressure sore has been estimated to range from \$500 to \$78,000, with the total burden on the health care system exceeding \$1.3 billion annually.¹⁰ Medicare will only reimburse for the care of stage III and IV pressure ulcers (see Table 64-1) that are documented on patient admission.¹¹ With average annual hospital costs of \$400,000 to 700,000¹² related to pressure ulcer management, adequate prevention strategies have significant financial implications.

The incidence and location of pediatric pressure ulcers vary with the study population. In a study of pediatric intensive care units, Curley et al¹³ found that 199 pressure sores developed in 86 of 322 patients (27%) on bed rest for at least 24 hours. Most of these sores (70%) were stage I; of the 60 stage II and III ulcers, 19 (32%) involved the head. In contrast, Baldwin¹⁴ conducted a national survey in which the incidence of pressure ulcers was 0.29%, and the prevalence was 0.47%. At our institution (Shriners Hospitals for Children—Chicago), from 1995 to 2004, 641 patients presented with spinal cord injuries. In 126 patients (20%) a pressure ulcer was documented at some point during this 9-year span; in 48 patients (7%) a pressure sore was the primary reason for admission. Based on this data set, the incidence of patients with spinal cord injury admitted to our institution over the study period was 0.8%.¹⁵

Some of the underlying causes leading to the formation of pressure sores are unique to the pediatric population. Although traumatic causes of paraplegia are common denominators in the development of both adult and pediatric pressure sores, children have congenital causes such as myelodysplasia, spina bifida, and/or myelomeningocele. These entities will be discussed in brief detail in the chapter. In contrast, adults more often have cerebrovascular accidents and chronic, debilitating neurologic illnesses.

Moreover, the anatomic distribution of pressure sores consistently differs between adults and children. In adults the most common sites are the ischium (28%), trochanter (19%), sacrum (17%), calcaneus (9%), and other sites (27%).¹⁶ In children, however, the relatively large size and weight of the head leads to a higher incidence of occipital pressure sores, and the use of lower extremity casting and orthotics increases the incidence of sores in the lower extremity. In children with an uncorrected kyphoscoliotic spine, pressure sores tend to develop anywhere along a bony prominence, which may lie in the cervical, thoracic, and lumbar region. Children with significant kyphoses also have problems with sitting because of altered loading of the pelvis and ischial tuberosities.

ETIOLOGIC FACTORS

The final common pathway in the development of pressure sores is the compression of soft tissues resulting in ischemia. If this pressure is not relieved, the eventual outcome is necrosis and ulceration. Although pressure is the single most important factor in the occurrence of these wounds, other local and systemic factors contribute; these include infection, malnutrition, obesity, insensate areas, immobility, paralysis, incontinence, and impaired cognition.¹⁷

Microinjection studies have demonstrated that systemic blood pressure is transmitted to the capillary level, with a mean transcapillary gradient of 20 to 40 mm Hg and a mean capillary pressure of 32 mm Hg.¹⁸ If compression between a bony prominence and a firm surface exceeds the capillary perfusion pressure, tissue ischemia results. In most people, ischemia is relieved by postural changes or by removal of external compression, and ischemia is reversible; however, in critically ill patients and those unable to change position or sense pressure, ischemia may progress to tissue necrosis. The exact duration of ischemia that results in ulceration is determined by the interplay of multiple factors, including tissue susceptibility, shearing forces, the amount of pressure, and the length of time it is applied.

The relationship between time and pressure for developing pressure sores was originally studied in animals¹⁹ (Fig. 64-1). Kosiak et al^{19,20} found that 70 mm Hg applied over a 2-hour period was sufficient to cause microscopic evidence of ischemia in dogs. Daniel et al^{21,22} confirmed these findings and in studies showed that 500 mm Hg of compression applied for 2 hours or 100 mm Hg applied for 10 hours was sufficient to cause muscle necrosis. Skin necrosis did not occur until 600 mm Hg was applied for 11 hours, suggesting that skin is more tolerant of ischemia than muscle. This is clinically significant for two reasons: First, sitting individuals have been shown to generate pressures as high as 500 mm Hg in the buttock region, and second, the highest pressures are generated deep, adjacent to pressure points such as bone, with less pressure at the

skin level.¹⁸ Skin is more resistant to ischemia, and the early visible changes in the skin may not reflect the actual injury in the muscle and deeper tissues. Therefore the cutaneous changes in a pressure sore have been described as the tip of an iceberg. Furthermore, Dinsdale^{23,24} demonstrated that friction can decrease the amount of pressure required to produce ulceration.

In a classic study, Lindan et al²⁵ placed patients on a compressible bed of springs and nails to measure the distribution of pressure in supine and sitting positions. Pressures of 40 to 60 mm Hg were recorded in the sacrum, heels, and buttocks while patients were supine, whereas pressures of up to 100 mm Hg were recorded in the ischium of patients in the sitting position²⁵ (Fig. 64-2).

Fig. 64-1 The inverse relationship between time (hours) and pressure (mm Hg) in the pathogenesis of pressure sore formation.

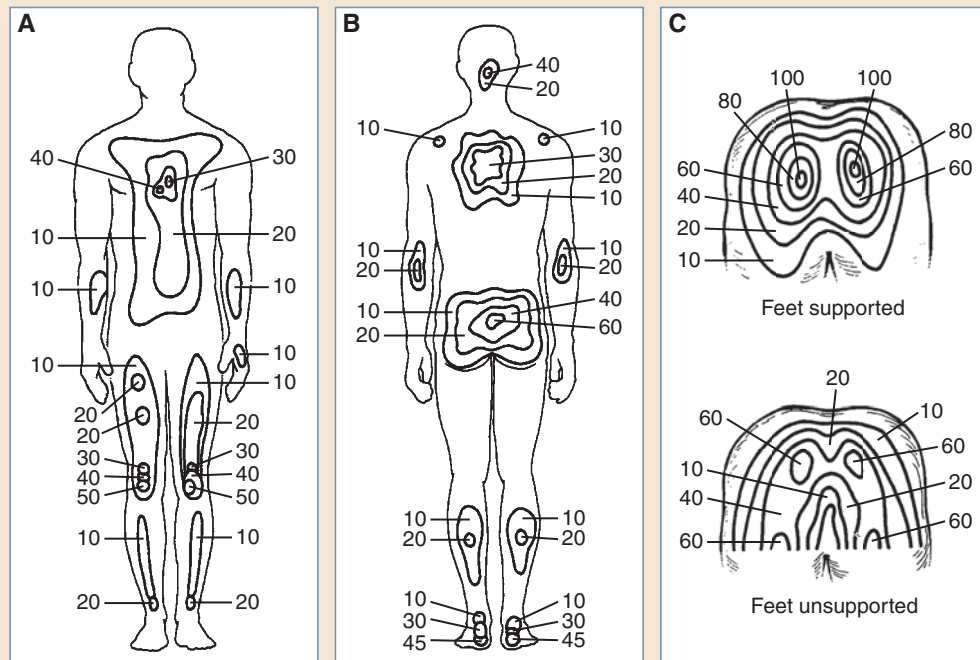

Fig. 64-2 Distribution of pressure (mm Hg) in a healthy adult. **A**, Prone. **B**, Supine. **C**, Sitting.

NEURAL TUBE DEFECTS

Neural tube defects (NTDs) are the second most common congenital defects, after congenital heart defects, and affect approximately 0.5 to 1 per 1000 established pregnancies worldwide.²⁶ The clinical severity of this class of defects varies greatly from uniformly fatal in utero (anencephaly and craniorachischisis) to asymptomatic (spina bifida occulta). The most common group of central nervous system anomalies that is compatible with life is spina bifida, a failure of vertebral arch formation that results in a bifid vertebral column. The most frequently observed form of spina bifida is myelomeningocele, in which the spinal cord extrudes into a meninges-covered sac filled with CSF. Despite preventive strategies, including folic acid supplementation, the incidence of myelomeningocele in the United States has stabilized at 3.4 per 10,000 births.²⁷ Myelomeningocele is generally compatible with life; however, neurologic impairment is seen below the level of the lesion and can result in numerous neurologic conditions, including paraplegia. Neural tube defects and their resulting paralysis/insensibility are a common reason pediatrics patients present with pressure sores. Moreover, these patients may present in the immediate postpartum period to plastic surgeons for closure of the myelomeningocele defect. In this situation, evidence suggests that local and regional flaps can be used to provide layered closure with good outcomes.²⁸ Fetal surgery has addressed these defects prenatally,²⁷ although currently, this treatment option is rare because of limited access and the dangers of fetal surgery.

PREOPERATIVE ASSESSMENT

History and Physical Examination

The diagnosis of pressure sores is relatively straightforward and based largely on the underlying disease process and a thorough examination of the wound. Various staging systems have been developed to facilitate serial examinations and communication among medical personnel. The National Pressure Ulcer Advisory Panel Consensus Development Conference²⁹ developed the most widely used system in 1989 and redefined it in 2007 (Table 64-1). However, such systems are subject to interrater variability and may not accurately describe wounds that appear superficial, but extend into the deep tissues.

All wounds should be examined for fluctuance, which may suggest a deep fluid collection that requires operative drainage. All necrotic tissue must be thoroughly debrided before initiating conservative or operative therapy. For insensate patients, this may be initiated at the bedside; however, definitive debridement is best performed in an operating room, where lighting and equipment for bony debridement and hemostasis are optimal. Osteomyelitis may be clinically suggested by a soft character to palpable bone at the base of a pressure ulcer; however, histopathology analysis provides the definitive diagnosis. The presence of osteomyelitis needs to be determined, because these wounds are more prone to breakdown and recurrence if not adequately debrided and treated with an appropriate course of antibiotics, usually prescribed by an infectious disease consultant.

Laboratory Tests and Imaging Studies

Several laboratory parameters, including erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) have been suggested to screen for the presence of osteomyelitis; however, these tests have poor specificity. The use of MRI to diagnose pressure sore-related osteomyelitis has been reported, with a sensitivity of 98% and a specificity of 89%.³⁰ However, in a 3-year follow-up, Huang et al³⁰ found that, despite 86% (49 of 57) positive MRI readings, only 48% of patients (20 of 42) required surgical debridement. The authors concluded that this resulted from the tendency for MRI to “overcall” the existence of osteomyelitis. Other imaging modalities, including

Table 64-1 Pressure Sore Stages

Stage	Title	Description
I	Nonblanchable erythema	Intact skin with nonblanchable erythema over a localized area, usually over a bony prominence, that lasts for more than 1 hour after pressure relief May be painful May indicate people at risk
II	Partial-thickness	Partial-thickness loss of dermis presenting as a shallow, open, red-pink ulcer without slough May also appear as an open or ruptured blister Should not be used to describe skin tears, tape burns, incontinence-associated dermatitis, maceration, or excoriation
III	Full-thickness loss, skin loss	Full-thickness tissue loss Subcutaneous possibly visible, but not bone, tendon, or muscle Depth varies by anatomic location
IV	Full-thickness tissue loss	All soft tissue destroyed, with exposed, directly palpable bone, tendon, or muscle, making osteomyelitis or osteitis likely
Additional categories	Unstageable/ unclassified Suspected deep tissue injury	Full-thickness skin or tissue loss of unknown depth: completely obscured by slough and/or eschar in wound bed Depth unknown: purple or maroon discoloration of intact skin or blood-filled blister caused by damage of underlying tissue from pressure and/or shear

CT and Tc⁹⁹ bone scanning have demonstrated limited utility in diagnosing osteomyelitis, with a sensitivity and specificity of 11% and 64% and 57% and 90%, respectively.³¹ CT and/or MR imaging may be useful in confirming deep fluid collections and/or sinus tracts that may not be apparent during surgical debridement. In a landmark paper, Lewis et al³¹ established histopathology as the benchmark for diagnosing osteomyelitis. They performed a Jamshidi core needle bone biopsy of 52 patients and reported a sensitivity and specificity of 73% and 96%, respectively.

NONOPERATIVE TREATMENT

Many stage I and II pressure sores can be treated with preventive or conservative measures aimed at halting progression of the wound and improving the local environment to maximize healing.

Preventive Management

The Braden Scale for Predicting Pressure Sore Risk is an instrument for pressure sore risk assessment that was developed for adults but is often used in children. It is a summated rating scale with scores ranging from 1 to 4 on five scales, and 1 to 3 on a friction and shear scale³² (Table 64-2). The best treatment for pressure sores is prevention, and this scale helps to alert the medical team to the potential risk of pressure sore development in immobilized patients. Because the single most important etiologic factor in the development of these wounds is pressure, relief of pressure is tantamount to prevention. Frequently, despite this information and application of meticulous prevention strategies, pressure sores develop. Therefore an aggressive multidisciplinary

Table 64-2 Braden Scale Components

	Sensory Perception	Moisture	Activity	Mobility	Nutrition	Friction and Shear
1 =	Completely limited (unresponsive)	Constantly moist	Bedfast	Completely immobile	Very poor	Problem
2 =	Very limited (responds to painful stimuli)	Very moist	Chairfast	Very limited	Probably inadequate	Potential problem
3 =	Slightly limited (responds to verbal stimuli)	Occasionally moist	Walks occasionally	Slightly limited	Adequate	No apparent problem
4 =	No impairment	Rarely moist	Walks frequently	No limitation	Excellent	

This is a summated rating scale with score possibilities ranging from 1 to 4 on the first five scales, and 1 to 3 on the friction and shear scale. The lower the score, the higher the ulcer risk potential.

approach is required that includes teaching patients and caregivers how to adequately relieve pressure and promptly recognize early skin changes.

Wound Care

The tenets of wound care are not specific to patient age, which has led to the extrapolation of adult treatment strategies to pediatric patients. For outpatient care, either air, foam, gel, or a water overlay/mattress supporting 19.5 kg/m³ is recommended for low-risk patients and should be immediately replaced with an air-exchange mattress at the first signs of hyperemia on a pressure point.³³ Similarly, all moderate- to high-risk patients should have a dynamic air-exchange mattress in the outpatient setting and be placed immediately on such a mattress on admission to the hospital.³³

Pressure sores are chronic wounds that incite a catabolic state. Nutritional supplementation is initiated to meet the increased protein and energy requirements to heal a pressure sore. Protein supplementation of 1.5 g/kg/day has been shown to not only improve the overall morbidity in these patients but also to enhance prevention of sore formation.^{34,35} Nutritional consultation and calorie counts should be implemented in all moderate- to high-risk patients.

Regardless of the pressure sore stage, we follow the surgical principle of moist wound healing.^{36,37} We often find that before a plastic surgical consultation, the initial approach to wound management was to “dry out” the wound, which tends to compromise tissue barriers and potentiate infection.

With recent advances in wound care products, myriad dressing choices are available to maintain a moist healing environment. These can be broadly classified as hydrocolloids and alginates, enzymatic agents, antimicrobials, and negative pressure wound therapy (NPWT). Characteristics of hydrocolloids (that make them favorable for localized care of pediatric pressure sores) are their ability to absorb exudative fluid, semipermeability, adhesiveness, and relatively infrequent need for dressing changes (every 3 to 5 days). Reducing the frequency for potentially painful dressing changes improves compliance and favors healing. These absorptive dressings should not be used for wounds with active infection, wounds with exposed tendon and/or bone, and

patients with diabetic foot ulcers. Although these dressings are costly, compared with some alternatives, the reduced need for dressing changes makes them cost-effective, compared with traditional gauze/saline-moistened dressings. Other disadvantages of these dressings include potential maceration of wound margins, limited wound visibility, and the foul odor that they produce.³⁸ Calcium derivatives of alginic acid, alginates, have absorptive qualities and the ability to solubilize and form hydrophilic gels in the presence of exudative wounds.³⁹

Recently, enzymatic debriding agents have been increasing in popularity. Ointments containing collagenase are effective in wounds with minimal necrotic debris (less than 20% of the total wound surface) *when used in conjunction with sharp debridement*. These enzymes successfully digest proteins from nonviable tissue, resulting in smaller peptides that are eliminated from the wound. We have found that long-term use of this ointment can result in the development of hypertrophic granulation tissue, which can subvert epithelialization of the wound.

When a wound has been successfully debrided and freed from necrotic and infected tissue, topical antimicrobial agents may be applied for local wound care. Silver sulfadiazine (Silvadene) and mafenide acetate (Sulfamylon) are topical antibiotics whose predominant application is in burn care. Similar to burns, pressure wounds are relatively avascular, and circulating systemic antibiotics often do not reach therapeutic levels at the target tissues when given parenterally. Topical antimicrobial agents provide high local concentrations while limiting systemic absorption and potential side effects.

Silvadene is the most widely used topical antimicrobial in the United States, largely for its ease of use, broad antimicrobial coverage, and relatively limited toxicity. It is relatively painless on application, but contains sulfa moieties; therefore it cannot be used in sulfa-allergic patients. Moreover, Silvadene can cause neutropenia with prolonged use, requiring close monitoring in patients with immunocompromised states. It can cause kernicterus in infants younger than 2 months of age and should not be used in these patients.

Sulfamylon has excellent penetration into avascular tissues, including cartilage and eschar. It has activity against *Pseudomonas aeruginosa*; however, adverse effects, including painful application, metabolic acidosis, and high osmolality that desiccates the wound tissue, limit the use of this agent to specific situations.

Bacitracin and mupirocin are topical antimicrobial ointments that provide a moist healing environment, usually with a low adverse-effect profile. So-called “triple” antibiotic ointments can occasionally cause a local rash from skin sensitivity. In such cases, we typically recommend vitamin A&D ointment to maintain moisture in the wound.

NPWT, referred to as *wound VAC therapy*, creates a negative pressure environment in which interstitial edema is decreased, thereby improving local circulation and angiogenesis and enhancing the formation of granulation tissue.^{40,41} Several reports have demonstrated a role for NPWT in the healing of pressure sores. Philbeck et al⁴² showed that closure of deep wounds with NPWT (0.23 cm²/day) is faster than with saline-moistened gauze dressings (0.090 cm²/day)⁴³ for treating trochanteric and trunk sores in conjunction with a low-air-loss bedding system. NPWT also reduced dressing-change frequency. NPWT devices should not be placed on contaminated or infected wounds. For patients with systemic signs of infection, the device is removed to allow a full examination of the underlying wound.

SURGICAL TREATMENT

Surgical Preparation of the Wound Bed

Unlike stage I and II sores, more advanced (stage III and IV) pressure sores usually require surgical intervention: debridement, reconstruction, or both. Determining when a wound is unresponsive to conservative therapy and may need flap reconstruction is a major decision. There

is no clear answer to this question. Several factors must be considered before making such a treatment decision, including the patient's wishes, comorbidities, nutritional status, and level of compliance with treatment; the location and characteristics of the wound; and the philosophy of the treating surgeon. At our institution, we consider a wound amenable to flap reconstruction when nutritional deficiencies and other medical comorbidities have been addressed and it has failed to respond further to conservative measures. Patients need to be motivated and compliant with the postoperative pressure-relief protocol to protect the newly treated pressure site and to prevent the development of a new sore.

Conway and Griffith⁴⁴ aptly described the basic tenets of the surgical management of pressure sores as follows:

- Excision of the ulcer, surrounding scar, heterotopic calcification, and underlying bursa
- Partial or complete osteotomy to remove the bony prominence
- Closure of the wound, which includes filling dead space with fascia or muscle flaps and resurfacing it with healthy tissue that can provide durable coverage over the wound

Adequate debridement that removes all devitalized tissue is a mainstay in treating pressure sores, whether they are to be reconstructed or allowed to heal by secondary intention. In select patients, including insensate paraplegics and quadriplegics, adequate debridement may be performed at the bedside; however, the bleeding risk and lack of available instruments limits the adequacy of such a procedure, and we reserve this option for minor wounds or poor anesthetic candidates. When possible, we prefer to debride in the operating room, where anesthesia, positioning, instrumentation, lighting, and assistance are optimized. This is particularly true for pediatric patients who tend to tolerate bedside procedures more poorly than adults. The appropriate anesthetic for a given debridement depends on several factors, including the patient's level of sensation, the positioning requirements, the anticipated length of surgery, and the potential need for blood products. We find that pressurized water irrigation (pulsed lavage) and hydrosurgical debridement (VersaJet, Smith & Nephew) are useful adjuncts that have been shown to reduce bacterial contamination.⁴⁵ Furthermore, Dorafshar et al⁴⁶ described the technique of methylene blue-guided debridement, which can provide visual confirmation of adequate debridement.

Intraoperatively, tissue cultures should be sent to determine the microbial pathogens that inhabit a wound and their antibiotic resistance patterns. We routinely send samples before and after debridement to determine adequacy of debridement and the presence of residual infection. Some centers use intraoperative quantitative cultures to ensure acceptable bacterial loads before reconstructing a wound or completing debridement. We do not routinely perform such cultures, because clinical assessment of a contracting, granulated wound tends to suffice. If osteomyelitis is suspected clinically, pathologic specimens of bone can be analyzed for the presence of osteomyelitis. At our institution, debridement and reconstruction are staged to facilitate assessment of the bacterial colonization and to obtain an infectious disease consultation for managing osteomyelitis, when present, before the definitive reconstruction. In the interim between the debridement and the reconstruction, the conservative measures mentioned previously are initiated to maintain a clean wound until the flap is closed.

Removal of Bony Prominences

The need to debride or excise bony prominences in an established pressure sore is derived from the pathophysiology that leads to wound formation. A broader bony prominence will better distribute the forces applied to the soft tissues, thereby helping to prevent a new sore from developing. Moreover, excision of bone will help to improve the wound excision and bacterial clearance and will decrease tissue requirements for wound closure.³¹ However, overly aggressive resection of bone can lead to complications, which include skeletal instability, bleeding, and redistribution

of pressure to adjacent areas with subsequent development of new sores. For example, a unilateral ischiectomy significantly increases pressure on the contralateral ischium and can increase the occurrence of contralateral pressure sores. Similarly, a bilateral ischiectomy increases perineal pressure and leads to difficult perineal wounds and, in extreme cases, urethrocuteaneous fistulas.⁴⁷ Therefore bilateral total ischiectomies should not be performed. In cases of recurrent unilateral ischial sores, the spine and tilt of the pelvis should be analyzed as the inciting cause of the sitting imbalance and may require corrective spine surgery.

Removal of the proximal femur for the treatment of trochanteric ulcers is sometimes necessary, especially if the joint is involved.⁴⁸ After a Girdlestone arthroplasty, the dead space of the acetabulum should be eliminated with fascia or muscle. A vastus lateralis flap is most commonly used for this purpose. For cases of chronic hip subluxation with an associated pressure sore, the acetabulum is typically already filled with chronic scar tissue, and a flap to fill the dead space is no longer necessary. Wound closure is aided if movement at the distal femur, which occurs as a result of removal of the proximal femur, is minimal. This movement can be controlled by various techniques, including external fixation devices, external traction devices, and abduction pillows supplemented with antispasmodic drugs.^{48,49}

SURGICAL TECHNIQUE

Certain principles of flap closure of all types of pressure sores are applicable for pediatric and adult patients. Dead spaces should be filled. Skin closures should be performed with acceptable tension. Flaps should maintain pulsatile blood flow after they are moved into position and should be reelevated for recurrences. Finally, flaps should be planned to keep the newly placed incisions off of the expected area of maximal pressure.

Sacral Pressure Sores

The surgical management of sacral pressure sores spans the reconstructive ladder and ranges from undermining and primary closure to free tissue transfer (Box 64-1). Tissue loss resulting from the ulcer may result in primary closure under tension and a significant recurrence rate. Higher on the reconstructive ladder, skin grafting has been attempted, but has shown poor outcomes because of fragility of the soft tissue coverage over pressure-bearing areas. Therefore the most common reconstructive procedures for sacral pressure sores are myocutaneous and fasciocutaneous flaps after debridement and coccygectomy.

Box 64-1 Reconstructive Options for Sacral Pressure Sores

- Primary closure
- Skin graft
- Turnover gluteus myoplasty
- Gluteus maximus myocutaneous flap*
- Gluteus maximus fasciocutaneous flap
- Sensory island flaps
- Intercostal island flaps
- Perforator flaps (superior gluteal)
- Free tissue transfer

*The most commonly used option at our institution.

The workhorse flaps for sacral pressure sore reconstructions are based on the gluteal vascular system and may be designed as muscular, myocutaneous, or fasciocutaneous flaps. Furthermore, they can be based superiorly or inferiorly; part or all of the muscle can be included in the design; and they may be advanced, rotated, or turned over. We commonly place nonambulatory patients in the prone position and make markings for a unilateral V-Y advancement myocutaneous flap (Fig. 64-3). After the skin is incised, dissection through the gluteus maximus muscle begins at the superior and lateral border near the trochanter. With a finger in the interspace between the gluteus maximus and medius, the lateral portion of the muscle toward the insertion is divided, followed by division of the inferior portion of the muscle under the lower skin incision. The muscle is elevated in a medial-to-lateral direction off of the sacrotuberous ligament, the main palpable landmark of the procedure. With the muscle completely mobilized laterally and inferiorly, the two vascular pedicles are identified, facilitating the final division of the muscle off of its medial attachments to the sacrum. With the flap completely dissected and the vascular pedicles identified, the wound can be thoroughly debrided without inadvertently injuring the pedicle or pedicles. This flap can easily provide enough coverage of the sacrum without tension and places the final incision line off the midline pressure point. In patients with very large wounds, this may be performed bilaterally; the only downside is that midline placement of the incision can increase susceptibility to breakdown in the long term. Closed-suction drainage and postoperative pressure-relief beds are an integral part of all pressure sore reconstructions.

Other available flap reconstruction choices include perforator flaps, fasciocutaneous flaps, and innervated flaps. Recently, perforator flaps based on the superior gluteal artery have received

Fig. 64-3 Gluteus maximus V-Y myocutaneous flap for reconstruction of a sacral pressure sore. **A**, Sacral pressure sore. **B**, A unilateral V-Y advancement myocutaneous flap based on the gluteus maximus is marked. **C**, The flap is raised. **D**, The flap is inset without tension. **E**, The wound is closed in layers over drains.

attention for pressure sore reconstruction, especially for ambulatory patients.^{47,48} The main advantage of these flaps is preservation of the gluteus maximus muscle.

Neural Tube Defects

Duffy et al⁵⁰ have used perforator flaps for coverage of myelomeningocele defects, with no short-term recurrences. Some investigators have performed fasciocutaneous flaps because of the often highly atrophic nature of the gluteal muscle in this patient population. Proponents of this approach argue that regardless of the muscle atrophy, the increased soft tissue bulk of the muscle may protect against recurrence of sores. Evidence in animal models suggests that myocutaneous flaps have improved outcomes in contaminated wounds.⁵¹⁻⁵³ Innervated flaps have been developed to restore protective sensation. These techniques include tissue expansion of sensate skin more cranial on the back, intercostal flaps to bring sensation to the sacrum, and the use of innervated free flaps.⁵⁴⁻⁵⁷ Despite the theoretical advantage of this approach, the clinical utility of innervated flaps is limited.

Ischial Pressure Sores

As with sacral pressure sores, several techniques are available for treating ischial pressure sores (Box 64-2), most of which are myocutaneous flaps. These include flaps based on the gluteus maximus, hamstring, tensor fascia lata, and gracilis muscles. Flaps based on the gluteus may be superiorly or inferiorly based and can carry skin from the gluteal or thigh areas. The inferior gluteus myocutaneous flap is based on the inferior gluteal artery and uses only the inferolateral portion of the muscle. In this procedure, anesthesia is induced, and the patient is placed in the prone position. After adequate debridement and a partial ischiectomy are performed, the gluteus muscle is mobilized and divided from its inferior and lateral attachments to allow medial movement and obliteration of the potential space over the ischium. The muscle is inset and the skin closed in layers over closed-suction drains.

The hamstring comprises the biceps femoris, semimembranosus, and semitendinosus muscles. Flaps based on the medial thigh skin have the advantage of bringing in padded tissue and the option of readvancement if needed for recurrences. The usual design is a V-Y myocutaneous advancement flap. The procedure is performed with the patient in the lateral decubitus or prone position. After the cutaneous incisions are made, the attachments of the short head of the biceps femoris are released, preserving the perforating segmental branches from the femoral artery.

Box 64-2 Reconstruction Options for Ischial Pressure Sores

- Primary closure
- Gluteus maximus myocutaneous flap*
- Hamstring myocutaneous flap*
- Tensor fascia lata myocutaneous flap
- Gracilis myocutaneous flap*
- Anterolateral thigh flap
- Rectus abdominis myocutaneous flap
- Free tissue transfer

*The most commonly used options at our institution.

Next, the long head of the biceps femoris tendon is divided from its insertion onto the fibular head. Similarly, the distal insertions of the semimembranosus and semitendinosus muscles are divided. A skin bridge is preserved medially. The entire hamstring unit is elevated off of the femur, attached only by segmental branches of the profunda femoris vessel. The flap is then advanced superiorly to close the defect in a tension-free manner. The wound is closed in layers over drains.

The tensor fascia lata can be used to close ischial ulcers, but the distal end of the flap, which is used to fill the wound, may have unreliable vascularity. In appropriate situations, however, this flap can be designed as a sensate flap to provide protective sensation with the lateral femoral cutaneous nerve.⁵⁸⁻⁶⁰ In a series of patients with pressure sores treated with an extended, sensory tensor fascia lata flap, no new or recurrent pressure sores were observed after 1 to 10 years of follow-up.⁵⁹

The gracilis muscle is supplied by the medial circumflex femoral artery. With the patient in a prone position, an incision is made in the posteromedial aspect of the leg and continued until the gracilis and adductor longus muscles are identified. Three aids to identifying the gracilis muscle are as follows⁶¹:

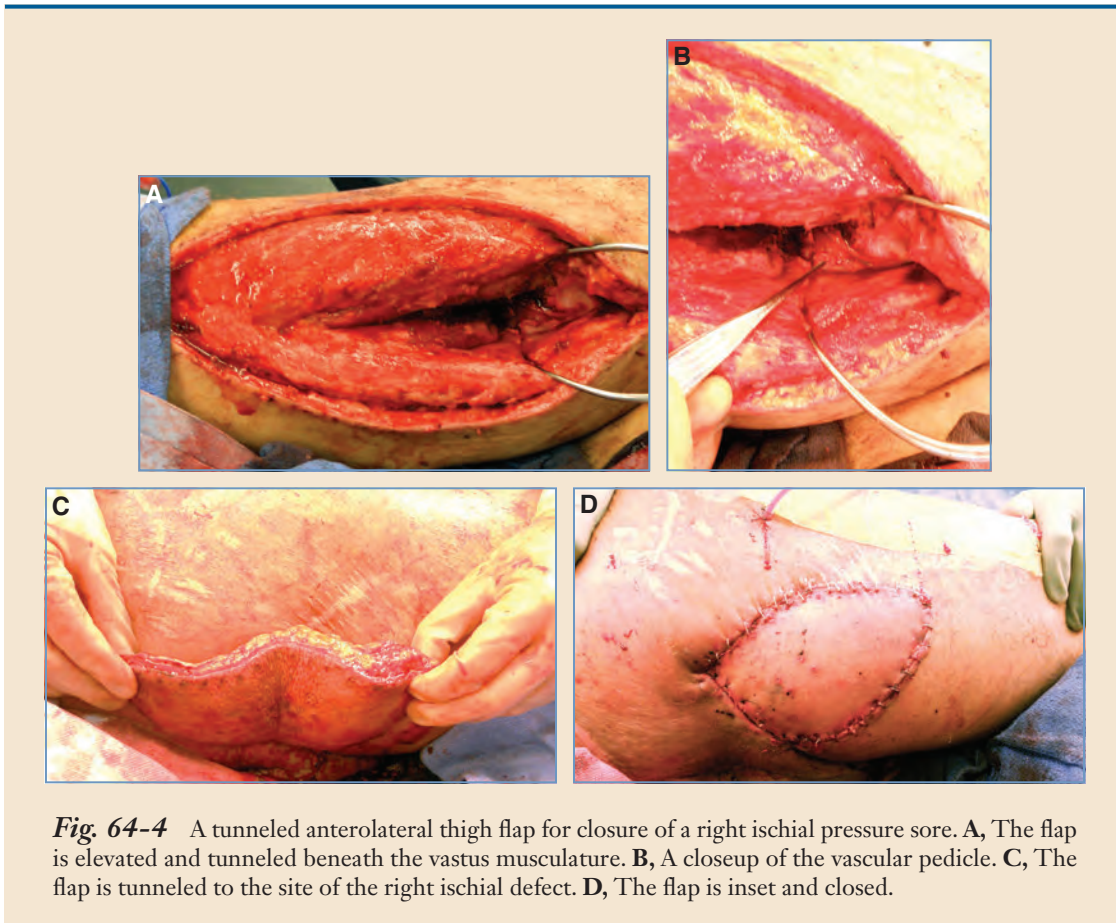

1. No superficial sensory or motor nerves are encountered during the dissection.
2. The dissecting finger can slide up and down the muscle on the deep and superficial surfaces without difficulty.
3. The muscle begins to taper and becomes triangular and tendinous two thirds of the distance down the thigh.

Once the muscle is identified, a skin paddle is designed and centered over the muscle. To prevent avulsion of the perforators, a suture is placed from the fascia of the skin island to the gracilis muscle. The dominant pedicle is exposed on the deep medial surface. After the gracilis muscle is detached from its tibial insertion, the flap is elevated from distal to proximal. If possible, the saphenous vein is kept in continuity proximally to improve venous outflow. Arterial inflow to the skin paddle is improved by including the adductor fascia with the flap. Flap movement is improved with division of the origin. After adequate debridement and a partial ischiectomy, the flap is inset. The gracilis flap has the advantage of being a true island flap, moving easily to cover the defect without tension and without a suture line over the central pressure point. The most significant disadvantage with this flap is occasional unreliability of the skin paddle.

An anterolateral thigh flap can be used for coverage of ischial sores by tunneling beneath the vastus muscle complex or subcutaneous tissues^{62,63} (Fig. 64-4).

Trochanteric Pressure Sores

Trochanteric pressure sores develop in patients who lie in the lateral decubitus position or sit in a significantly slouched posture in a wheelchair for prolonged periods of time. The risk is increased in patients with significant hip flexion contractures. As described previously, a Girdlestone arthroplasty with a vastus lateralis muscle flap should be considered if the hip joint is involved with the wound. However, a femoral head resection causes altered weightbearing on the proximal femur and ischium, and should not be performed if possible. Of the many reconstructive options for closure of trochanteric sores, the most commonly used are the tensor fascia lata or vastus lateralis myocutaneous flaps (Box 64-3). A tensor fascia lata flap can be transferred as muscle only, as muscle and skin, as an island flap, or as a free flap. It has the potential for sensation by the lateral femoral cutaneous nerve (L1-3) if the level of the spinal cord injury is below L3. Dissection begins at least 10 cm from the proximal knee to ensure good vascularity of the tip of the flap. Doppler signals are located on the skin paddle, and the skin incisions are made. The incisions are deepened through the fascia lata, and the pedicle is identified as it emerges from

Box 64-3 Reconstructive Options for Trochanteric Pressure Sores

*The most commonly used options at our institution.

under the rectus femoris to enter the tensor fascia lata muscle. The rest of the flap elevation off of the vastus lateralis is straightforward. The donor site is closed in V-Y fashion, primarily, or with a skin graft for large flaps.

The vastus lateralis is supplied by the descending branch of the lateral circumflex femoral artery and is the largest of the quadriceps muscle group, extending from the proximal femur to the patella. The flap can be raised as muscle only or as muscle and skin. The patient is placed in the lateral

decubitus position, and an incision is made on the anterolateral thigh from a point 10 cm below the anterior superior iliac spine to the lateral condyle of the femur. If a skin paddle is to be included, the incisions should be made at the borders of the island. The vastus lateralis is then identified and raised from distal to proximal. Care is taken to visualize and preserve the dominant pedicle that travels underneath the rectus femoris and not to elevate the vastus intermedialis (thereby exposing the femur). The flap is rotated into the wound and closed in layers over drains.

Scalp

Scalp pressure sores are usually stage I and II sores, as demonstrated by loss of hair follicles. These sores are seen more often in pediatric patients because of the larger relative size and weight of the head in this age group. Pressure sores of the scalp typically close with local wound care, consisting of pressure relief, cleaning with soap and water, removal of hair in the region close to the wound, and the application of topical antimicrobial agents. Surgical intervention is rarely required for these wounds, but when necessary, local rotation or advancement flaps are usually sufficient.

POSTOPERATIVE CARE

Flap closure of a pressure sore is one component of a comprehensive care plan that is essential for preventing postoperative complications, most notably dehiscence, partial or total flap necrosis, and recurrence. The factors that contributed to the original formation of the sore must be recognized and modified, and the patients and caregivers need to be informed about prevention. Optimizing nutrition and addressing medical comorbidities that may interfere with wound healing (diabetes and smoking) are critical. Furthermore, we employ a standard postoperative protocol at our institution that is aimed at pressure relief and a gradual return to activities of daily living.

The timing and degree of postoperative care regimens vary from one institution to another, but they all have in common pressure relief (by frequent transfers or special mattresses such as a Clinitron bed [Hill-Rom]), wound toilet to prevent maceration of the operative site, adequate drainage to remove serous fluid, and often antibiotics (based on the intraoperative cultures). At Shriners Hospitals for Children–Chicago, the following protocol is initiated after wound flap closure:

- The child is immediately transferred from the operating table to a Clinitron bed.
- Drains are placed on bulb suction and monitored for output, and these drains are kept in place for an average of 14 days.
- The medical staff meticulously cares for the skin, and the wounds are assessed for breakdown, scabs, drainage, and erythema.
- After 14 days in a Clinitron bed, a sitting protocol is initiated on an air mattress (Flexicair bed; Hill-Rom) (Table 64-3).
- If the surgical site is healing properly during the sitting protocol, the patient is allowed to sit with proper pressure-relief devices and pressure-relief methods (such as bending forward and elevating the buttocks, or turning while supine).
- Children are typically discharged 2 to 3 weeks after flap closure, with the sitting times explicitly listed for the patient and caregivers.
- Follow-up visits are scheduled within 2 weeks of discharge and monthly until the wounds are stable and healed.

Table 64-3 Sitting Protocol After Pressure Sore Flap Reconstruction

Week	Postoperative Day	Protocol
1-2	1-14	Bed rest
3	15-18	Sit 20 min QID
	19-21	Sit 40 min QID
4	22-24	Sit 60 min QID
	25-28	Sit 90 min QID
5	29-35	Sit 120 min
6 and beyond	36+	Sit maximum of 2 hr QID followed by 60 min of pressure relief until cleared by operating physician

QID, Four times a day.

TREATMENT OUTCOMES

Operative Complications

Acute complications after pressure sore debridement and reconstruction are similar to those of any surgical procedure and include pulmonary and cardiac complications, wound dehiscence, infection (wound and urinary tract), and hemorrhage. With sound surgical technique, many of these complications can be prevented; the main complication after pressure sore reconstruction is recurrence. Some studies have reported recurrence rates of up to 70%, although most of these studies have been performed in adult populations.⁶⁴ Because of the differences in underlying causes and medical comorbidities, the rate is probably much lower in the pediatric patients. A study from the Children's Hospital of Philadelphia reported a 5% recurrence rate in a series of 20 pressure sores.⁷ A 9-year retrospective review at Shriners Hospitals for Children–Chicago revealed a recurrence rate of 10%, with a follow-up ranging from 1 to 7 years.¹⁵ Regardless of the method of treatment, we think that key steps in reducing pressure sore recurrence are adequate preventive pressure-relief strategies; routine health care visits for evaluation and early detection of compromised soft tissue; and education of patients and caregivers.

Complications of Chronic Wounds

Chronic wounds are associated with several long-term sequelae. In pressure sores with underlying osteomyelitis, secondary amyloidosis may develop with end-stage renal disease as a consequence. In 1828 Marjolin described carcinomatous changes in burn scars.⁶⁵ In today's terminology, a *Marjolin ulcer* denotes malignant degeneration of chronic wounds, most commonly into squamous cell carcinoma. Unlike other epithelial tumors of this type, Marjolin ulcers tend to be more aggressive with early metastases and a morbid clinical course. In one series, 65% of patients developed metastases within 3 years of diagnosis, with a 2-year survival rate ranging from 66% to 80%. Prevention of systemic diseases, including amyloidosis and wound-related malignancies, is another reason to prevent chronic wounds in children.

FUTURE TREATMENT MODALITIES

Cytokine therapies have received attention in the wound-healing literature in recent years. Topical application of these agents, particularly platelet-derived growth factor (PDGF) (as recombinant human [rh]-PDGF-BB or becaplermin gel), has been studied extensively. Several randomized, double-blinded clinical trials have demonstrated efficacy of this agent as independent or adjunct therapy in healing chronic wounds.⁶⁶⁻⁶⁸ Kallianinen et al⁶⁶ showed that 92% of wounds pre-treated with PDGF remained closed after “salvage” surgery, compared with 0% of placebo-treated wounds in control subjects. Once-daily application of this mitogenic cytokine, at a concentration of 100 µg/g, not only significantly increased the incidence of complete wound closure (at least 90%) in another phase II randomized study but also significantly reduced the median relative ulcer volume, compared with placebo-gel counterparts.⁶⁷ Despite this evidence, PDGF-based therapies are not commonly used in many centers because of their high cost. Other emerging technologies in tissue engineering (for example, cultured keratinocytes) and molecular biology will probably contribute to improved outcomes in the management of pressure sores.

KEY POINTS

- Adult and pediatric pressure sores have in common unrelieved pressure.
- Children develop pressure sores in the same manner as adults but with some different anatomic distributions.
- Paramount to the successful nonoperative or operative treatment of pressure sores is patient education coupled with a multidisciplinary approach.
- Prevention is the most effective approach to pressure sore management.
- Ideal candidates for flap treatment are motivated, have a clean wound that has failed to close despite appropriate nonoperative management, and understand their role in wound care and long-term pressure relief.
- Successful flap treatment of pressure sores includes adequate debridement of inflamed and thickened tissue, removal or reduction of bony prominences, and full flap mobilization on the pedicle for a tension-free wound closure.
- The postoperative management of pressure sores determines long-term outcomes and recurrence rates.
- Evidence shows that surgical treatment of pressure sores in children leads to lower recurrence rates than in adults and may be preferable to nonoperative management.

The authors conducted a retrospective analysis of 19 consecutive patients who had surgical treatment of 25 stage III and IV pressure sores over a 12-year period. The mean follow-up was 5.3 years. The recurrence rate was 5%, showing that surgical reconstruction of pediatric pressure sores can be successful and provide long-term skin integrity.

In this 15-year, single-institution study of 45 consecutive patients, composite soft tissue coverage of myelomeningocele defects, including muscle-fascia and skin, resulted in successful closure in nearly all patients. The incidence of CSF leakage was 0% and only one reoperation for skin necrosis was needed. They concluded that locoregional flaps should be used in all cases of myelomeningocele closure.

Vascularized Composite Allotransplantation in the Pediatric Population

Siba Haykal • Ronald M. Zuker

Despite substantial advances in reconstructive surgery, many pediatric conditions do not have acceptable solutions. These include significant facial deformities (congenital and acquired) that cannot be satisfactorily reconstructed, even with current advanced techniques. Abdominal wall deficiencies may limit potential small bowel allotransplantation. Reconstruction of extensive anomalies and traumatic loss of the extremities is particularly challenging. Current techniques often fall short of successful reconstruction for patients with laryngeal defects, uterine anomalies negating the possibility of childbirth, and micropenis.

In this chapter, we will present a brief history of vascularized composite allotransplantation (VCA) and attempt to place this new surgical tool in perspective. We will discuss the scientific basis of VCA and the research performed to date. The chapter will focus on some of the specific issues that apply to children. What are the effects on growth and function of the allograft? How does immunosuppression affect a growing child? What are the ethical concerns regarding pediatric transplantation? Last, we will explore the potential indications for pediatric VCA.

HISTORICAL PERSPECTIVE

Sushruta,¹ the founding father of surgery, described the surgical transfer of tissue from one location to another. In the *Sushruta Samhita*—Sushruta's compendium, written around 600 BC—he described the process of nasal reconstruction. The nose was a symbol of dignity and respect in ancient India and was frequently amputated in those who committed criminal offenses, adulterers,

Box 65-1 Sushruta's Original Sanskrit Description of Nasal Reconstruction

"The portion of the nose to be covered should be first measured with a leaf. Then a piece of skin of the required size should be dissected from the living skin of the cheek and sutured back to cover the nose, keeping a small pedicle attached to the cheek. The part of the nose to which the skin is to be attached should be made raw by cutting the nasal stump with a knife. The physician should then place the skin on the nose and stitch the two parts swiftly, keeping the skin properly elevated by inserting two tubes of erand (the castor oil plant) in the position of the nostrils so that the new nose gets proper shape. The skin thus properly adjusted, should then be sprinkled with a powder of licorice, red sandalwood and barberry plant. Finally it should be covered with cotton, and clean sesame oil should be constantly applied. When the skin has united and granulated, if the nose is too short or too long, the middle of the flap should be divided and an endeavor made to enlarge or shorten it."

From Saraf S, Parihar R. Sushruta: the first plastic surgeon in 600 B.C. Internet J Plast Surg 4, 2006.

Fig. 65-1 Sushruta—the founding father of surgery.

and prisoners of war. Tissue was transferred from the cheek to the nose, and Sushruta's description from two and a half centuries ago reads like a modern operative note, including the description of a template for the defect and a complex postoperative dressing (Box 65-1 and Fig. 65-1).

This procedure was modified, probably by one of his many students, as a transfer of an arterialized flap from the forehead—the classic Indian rhinoplasty¹ (Fig. 65-2). After generations, the concept and description of this procedure were brought to Europe, and distant transfers evolved, as described by the pioneers of reconstructive surgery Tagliacozzi and Curtorum² (Fig. 65-3). They said, "We restore, rebuild, and make whole those parts which nature hath given, but which fortune has taken away. Not so much that it may delight the eye, but that it might buoy up the spirit and help the mind of the afflicted."

The "first" recorded case of VCA is thought to be the legendary story of Saints Cosmas and Damian, twin brothers and physicians. Their famous, miraculous exploit was the grafting of a

Fig. 65-2 Modification of rhinoplasty using an arterialized forehead flap—the classic Indian rhinoplasty—instead of a cheek flap. **A**, Preoperative markings. **B**, The flap is transferred into position.

Fig. 65-3 The original drawing of a so-called Italian method of rhinoplasty. The Indian surgeons of antiquity performed this distant transfer of vascularized tissue, which reconstructive surgeons of the twentieth century expanded into a free vascularized tissue transfer.

Fig. 65-4 Depiction of Saints Cosmas and Damian by artist Ambrosius Francken the Elder in the late sixteenth century. They are said to have carried out the first recorded VCA by transferring tissue from one person to another.

leg from a recently deceased Ethiopian to replace their patient's ulcerated leg³ (Fig. 65-4). The outcome of the surgery is unknown, but the Christian twins and their younger, collaborating brother were put to death by the Roman authorities for heresy.

The work of Billingham et al⁴ on World War II burn victims led to the concepts of graft rejection and acquired immune tolerance. A badly burned patient who had received skin grafts from the same donor on two different occasions rejected the second graft more rapidly than the first graft, suggesting immunologic memory. Rejection could be adoptively transferred in animals if they received the sensitized blood cells but not serum of the original graft recipient. These studies laid the foundation of immune tolerance and gave hope to patients and researchers that the immune system might be manipulated to develop tolerance to foreign tissue in the complete absence of drug-induced immunosuppression.

Murray,⁵ an American plastic surgeon who won the Nobel Prize for his work in organ transplantation, promoted the involvement of plastic surgeons in the field of transplantation. He emphasized the importance of balancing the immunologic and physiologic factors of organ transplantation and proposed a relative scale of antigenicity of tissues and organs. The immunologic factors included donor antigenicity, host responsiveness, genetic compatibility, and the immunosuppressive regimen. The physiologic factors were the function of the donor kidney, the preservation method, the ischemic interval, the anastomoses of vessels and the ureter, the lung-liver-reticuloendothelial function, and infection. According to his relative scale of antigenicity of tissues and organs, the skin and lungs are the most antigenic, the liver and heart are less antigenic, and the kidneys and pancreas are the least antigenic.⁵ Murray recognized the

Fig. 65-5 Matthew Scott received a new hand in 1999 in Louisville, Kentucky. It was the first successfully functioning hand transplant.

importance of identical twins having identical immunity and successfully carried out the first kidney transplant.⁶ He later used radiation to reduce rejection and introduced immunosuppressive drugs to control rejection, ushering in the new world of organ transplantation.

In 1963 the first hand transplantation was performed in Ecuador, but it survived for less than 3 weeks because of ineffective immunosuppressive therapy.^{7,8} Advances in immunosuppression therapy led to more innovations. A human hand allograft was performed in Lyon, France, in 1998 but was rejected and removed 29 months postoperatively, because the patient did not comply with the immunosuppressive treatment.^{9,10} A team of plastic and orthopedic surgeons led by Breidenbach^{11,12} and Tsai performed the first successful hand transplant in Louisville, Kentucky. The patient was carefully selected on the basis of anatomic need, rehabilitation potential, psychosocial stability, and assurance of maintenance of immunotherapy. The result was superb, far beyond what could be achieved with a prosthesis (Fig. 65-5). However, this functional success had a price. With immunosuppressive therapy, one of the Louisville patients developed diabetes, and another developed avascular necrosis of the hip.¹² In 2005 a partial face was successfully transplanted in a 38-year-old woman.¹³ The result was remarkably far better than could be achieved with current reconstructive surgery techniques (Fig. 65-6). Since then, more than 28 facial transplants¹⁴ and more than 100 upper extremity transplants¹⁵ have been performed around the world. In 2012 a 19-year-old boy received a total face transplant in Turkey.¹⁶ He is the youngest successful face transplant recipient to date.

In 2015 the first pediatric VCA was performed in an 8-year-old boy with quadrimembral amputations from sepsis. The Philadelphia team, led by Scott Levin (Fig. 65-7; see Fig. 65-12), carried out the surgery. The early results are promising and may set the standard for pediatric extremity VCA in the future. We have learned from the current experience with adult patients that these VCA procedures can achieve results not possible by any other means. Critical factors in patient selection include anatomic need, rehabilitative potential, psychosocial stability, and solid support systems. Surgeons should be confident that patients can comply with the immunosuppressive regimen. The survival of the patient, the survival of the allotransplant, and the function of the tissue components depend on these factors.

Fig. 65-6 Isabelle Dinoire received the first face transplant in 2005. She has a remarkable aesthetic and functional result.

Fig. 65-7 Dr. Scott Levin led the team that performed the first successful VCA in a child. He is seen with his young patient in the early postoperative period. (Courtesy of Children's Hospital of Philadelphia.)

Other VCA tissues have been transplanted, with results varying from excellent (as in the Scandinavian experience with uterine transplants¹⁷) to complete failure (as in the Chinese experience with a penile transplant¹⁸).

THE SCIENCE OF VASCULARIZED COMPOSITE ALLOTRANSPLANTATION

VCAs are composed of many different tissues, including skin, fat, muscle, nerve, vessel, and bone. They differ from solid-organ allografts such as the heart, lung, and liver in many ways. Some are highly visible, such as face and hand allografts. They are not life saving, but rather life enhancing.¹⁹ Thus new issues for discussion arise regarding indications and ethics of an elective procedure, with significant, long-term complications revolving around lifelong immunosuppression. This is even more controversial in children, as discussed later in the chapter. In this section, we review the evolution of our understanding of the immunology associated with VCA and the cur-

Fig. 65-8 The skin epidermis is considered a privileged target of graft rejection, because it contains numerous specialized APCs, such as Langerhans cells, and nonspecialized APCs, such as dendritic cells. (MHC, Major histocompatibility complex.)

rent basic science research in this field. Presently, questions regarding immunology in VCA are the following:

- Is VCA feasible considering the high antigenicity of the skin component?
- Can VCA be performed without the use of highly toxic doses of immunosuppressive agents?
- Can VCA patients develop tolerance to reduce or eliminate immunosuppression?

In 1957 Billingham and Brent²⁰ discussed the concept of *split tolerance*. It refers to simultaneous tolerance to one tissue and rejection of another from the same donor. Skin grafts almost always fail before any other transplanted tissue or organ.²⁰ The secondary vascularization required for acceptance of conventional skin grafts upregulates cytokines, leading to rejection. The skin is highly immunogenic, because it contains a large number of specialized antigen-presenting cells (APCs), such as human leukocyte antigen class II APCs (Langerhans cells), and nonspecialized APCs, such as dendritic cells. Therefore the epidermis is considered a privileged target of graft rejection²¹ (Fig. 65-8).

In 1991 Lee et al²² published a key paper in the field of VCA. They transplanted donor rat limbs into rat recipients. The limbs were transplanted either as a whole or after division into different components (skin, subcutaneous tissue, muscle, bone, and blood vessel). They noted that different components caused different responses at a cellular or humoral level. Skin was not the most immunogenic. The limbs transplanted as a whole caused a lower response, compared with individual components. The authors hypothesized that this was the result of a “consumption” phenomenon and antigen competition. They also observed a higher immune response toward the vascularized limbs, compared with the nonvascularized limbs. This focused attention on split tolerance.

The ultimate goal is to induce tolerance. This can be achieved through preconditioning regimens that “prepare” the host to receive donor tissues and organs. Three main concepts emerge: macrochimerism, microchimerism, and mixed chimerism. In macrochimerism, the donor pluripotent hematopoietic stem cells engraft in the recipient and produce all its lineages, including the donor immune system; a new, hybrid immune system is established in the recipient and

Fig. 65-9 Donor hematopoietic stem cell transplantation generates mixed chimerism by producing cells from the donor and the recipient. Presentation within the thymus leads to clonal deletion of donor-reactive and recipient-reactive thymocytes, producing central tolerance. Peripheral tolerance is obtained through education and production of regulatory T cells.

reciprocal bidirectional donor, which leads to host tolerance.²³ In microchimerism, passenger leukocytes from the transplanted allograft interact with the recipient leukocytes and are hypothesized to lead to clonal exhaustion, resulting in donor-specific tolerance; this may explain how some transplant recipients require significantly reduced levels or no immunosuppression at all over time.²³ In mixed chimerism, the donor and recipient hematopoietic systems coexist. In humans, bone marrow transplantation–induced mixed chimerism has been shown to confer acceptance of donor-specific skin and kidney allografts without long-term immunosuppression. Mixed chimerism prevents chronic rejection, which is the major cause of late graft loss. This is probably associated with a lower incidence and severity of graft-versus-host disease, retains immunocompetence for primary immune responses, and can be induced through nonmyeloablative conditioning²⁴ (Fig. 65-9).

After conditioning is carried out to suppress alloreactivity and to facilitate engraftment, donor hematopoietic stem cell transplantation is performed. Engraftment of donor hematopoietic stem cells in recipient bone marrow results in persisting mixed chimerism and a self-renewing source of progeny for education in the thymus. Coexistence of donor and recipient antigen-presenting cells in the thymus results in clonal deletion of donor-reactive and recipient-reactive thymocytes (central tolerance), with tolerance of transplanted organs or tissues and a reduced risk of graft-versus-host disease. Presumably, alloreactive thymocytes escaping deletion are controlled by T regulatory cells (peripheral tolerance), educated either in the thymus or within transplanted tissues (see Fig. 65-9). Why is the immunogenicity of the whole limb less than that of the skin alone? One possibility is that VCAs (particularly limb transplants) function as a vascularized bone marrow transplant.^{25,26}

Animal and Preclinical Models of Vascularized Composite Allotransplantation

Several animal models have been developed to investigate the immune responses to different VCA components. Hettiaratchy et al²⁷ performed heterotopic limb transplantation across both haploidentical and fully mismatched major histocompatibility complex barriers after a nonmyeloablative, radiation-free conditioning protocol. Limb transplant and donor hematopoietic cell infusion with either bone marrow or cytokine-mobilized peripheral blood mononuclear cells (CMPBMC) were performed while animals received a 30-day course of cyclosporine A. Split tolerance was observed, and skin was rejected by day 60. Mixed chimerism was detected in recipients of CMPBMC but not in bone marrow recipients; however, animals from both groups developed tolerance of musculoskeletal tissues and *in vitro* evidence of donor specific unresponsiveness. Furthermore, all animals with demonstrable chimerism developed cutaneous graft-versus-host disease approximately 70 days after the transplant. All cases resolved with a short course of cyclosporine or methylprednisolone; however, this was a significant complication that probably would not be considered acceptable in a clinical setting.

VCAs are an ideal form of bone marrow transfer, because the graft itself provides the stromal microenvironment for proliferation of donor cells. However, studies in large animals failed to demonstrate lasting chimerism.²⁴

Because the graft is visible, biopsy samples are easily obtained at different stages but can often lead to bias. For example, Cendales et al²⁸ proposed the Banff grading system in which, despite the histologic evidence of infiltration, some changes do not require an increase in the immunosuppressive dose. They were able to assess the phenotype of infiltrating cells that led to the identification of facilitating and tolerogenic cells.²⁹

VCA appears to be feasible. As a whole organ in combination with other tissues, the skin does not behave the same as when it is transplanted alone. Advances in solid-organ transplantation, particularly immunosuppressive techniques, will help in preventing the use of highly toxic doses

in VCA. The preclinical large animal studies are promising with regards to tolerance, which remains transient in the clinical cases of VCA.

The current focus of research is on cell therapy, adhesion molecules, chemokines and cytokines, and tertiary lymphoid organs, with the ultimate goal of tolerance.

ADVANCEMENTS IN IMMUNOSUPPRESSION

The growth of solid-organ transplantation parallels the emergence of immunosuppressive drugs. In the 1960s azathioprine and prednisolone were used in renal transplantation.³⁰ Polyclonal antithymocyte globulin preparations became available in the 1970s.³⁰ The introduction of cyclosporine A in the early 1980s improved 3-year graft survival. Subsequently, the use of tacrolimus and sirolimus led to the current 1-year survival rate of 94% for kidney transplants, and monoclonal antibodies have led to steroid-sparing immunosuppression³⁰ (Box 65-2).

Currently, most immunosuppressive regimens include the following:

- Polyclonal antibodies: antithymocyte globulins or antiinterleukin 2 receptor antibodies (daclizumab and basiliximab)
- A triple-drug maintenance protocol consisting of a calcineurin inhibitor (tacrolimus), an antiproliferative agent (mycophenolate mofetil), and corticosteroids (prednisolone)³⁰ (Fig. 65-10)

The adverse effects and complications of these medications include the following:

- Opportunistic infections
- Malignancy
- Posttransplant lymphoproliferative disorders
- Hypertension
- Dyslipidemia
- Diabetes mellitus
- Renal insufficiency

However, without adequate immunosuppression, the risk of developing chronic rejection and graft loss is almost certain.

Pediatric solid-organ allograft survival rates have improved over the past years because of advances in immunotherapy regimens. Despite such advances, the failure rate is 25% to 35%.³¹ Many patients will require a second transplant, because transplantation rates for chronic rejection range from 5% to 25% for all organ types.³² Long-term immunosuppressive therapy exposes patients to an increased lifetime risk of infections, diabetes, hypertension, dyslipidemia, cardiovascular disease, renal insufficiency, and malignancy. Nonadherence to medication is a common cause of graft dysfunction and loss among the adolescent transplant recipients. Rejection episodes, hospitalizations, and medication adverse effects not only contribute negatively to the quality of life of the patients but can also affect growth and development and psychosocial stability.³³

Box 65-2 Five Broad Categories of Immunosuppressants

1. Glucocorticoids
2. Cytostatic agents
3. Antibodies
4. Drugs acting on immunophilins
5. Other drugs

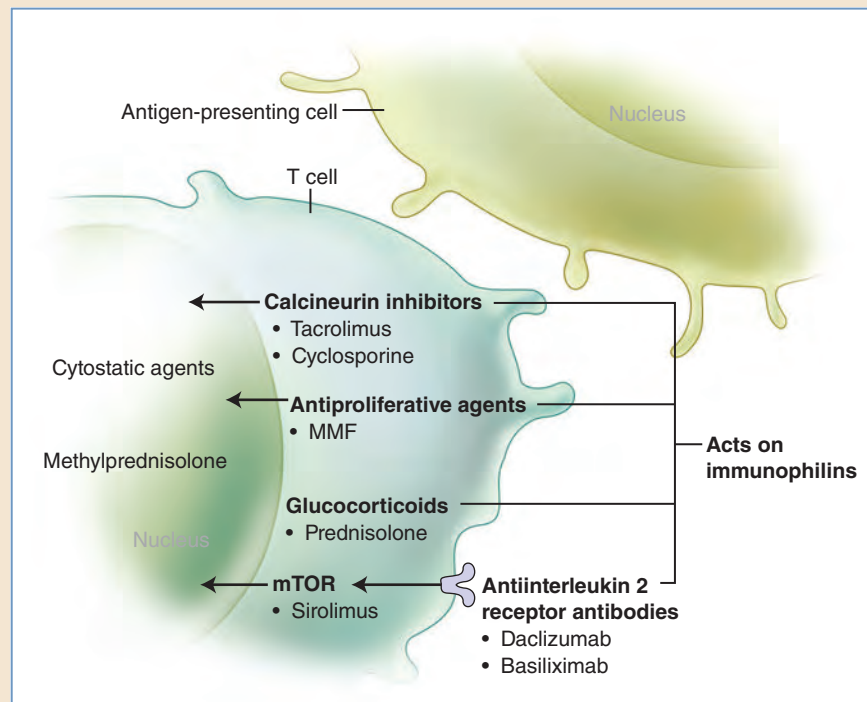

Fig. 65-10 Mechanism of action of different immunosuppressive medications. (MMF, Mycophenolate mofetil.)

The first reports on suspected chronic rejection in hand transplantation are now emerging, indicating amputation of the transplanted limb.³⁴ Chronic rejection in face transplant recipients has not been reported. (The longest follow-up is 8 years.) The effects of such a complication could prove to be devastating and potentially fatal.

SPECIFIC ISSUES FOR VASCULARIZED COMPOSITE ALLOTRANSPLANTATION IN CHILDREN

Much of what we anticipate for VCA in children is predicated on our experience in replantation and free tissue transfer, especially regarding growth and function. Similarly, the effects of immunosuppression in children are based on our solid-organ transplant experience. Several unknowns exist in the field of ethics, about which we can only hypothesize. Answers to many of these ethical concerns will evolve. This section will discuss the specific issues of VCA in children and conclude with a list of complex, insolvable problems for which VCA may be indicated.

Growth and Function of Allograft

Good evidence from our replantation experience shows that the growth of the replanted part will continue in an uninterrupted fashion if the growth plate is uninjured and has undergone only minimal ischemia. The growth plate is known to be quite sensitive to ischemia; therefore replantation in a timely fashion has always been critical in growing children. We anticipate that VCA

Fig. 65-11 Long bone growth in a transplant may be nearly normal if both the metaphysis and the epiphysis are revascularized. This radiograph shows bony union and maintenance of structure.

will have a similar pattern. In free tissue transfer of growth plates from one part of the body to another, such as in a toe transfer or a fibular transfer, growth will continue as it would have in the original location of the transplant. Tissues will grow at a programmed rate. This emphasizes the importance of transplanting like to like tissue of compatible age that is projected to have similar height and weight as the recipient.

Bowen et al³⁵ conducted research showing that long bone growth is “near normal” or “about 90% of normal” if both the metaphysis and the epiphysis are revascularized (Fig. 65-11). These studies were conducted years ago and have been reconfirmed. Therefore we agree that transplants will grow at near-normal rates.

The next question is, “Will the transplant function?” The International Registry on Hand and Composite Tissue Transplantation contains cumulative data regarding the function of hand transplants.¹⁰ More than 10 years of outcome data is recorded. The data for initial function and long-term improvement are very positive. The Registry has shown that the Disability of the Arm, Shoulder, and Hand scores decrease over time, indicating improved function and reduced disability. Similarly, the Hand Transplantation Score System improved initially and continued to improve steadily during the 10-year period¹⁰ (Table 65-1). This indicates ongoing improvement in hand function after the transplant. Based on the results, we think that where a part was present at birth and has been lost from trauma or disease, function can be regained through VCA.

Where There Was Cortical Representation at Birth In some pediatric conditions, a part is not present at birth. The usefulness of VCA in these patients is questionable. However, we think that where cortical representation is present, for example, in an intrauterine amputation with amniotic band syndrome, this cortical component will reform readily with a transplant. The cortical representation that was present previously should return to its previous state after a VCA, and appropriate cortical representation and near-normal integrative function should develop. Lundborg³⁶ documented this phenomenon, which is thought to be particularly useful in younger patients.

Where There Has Never Been Cortical Representation It is not known whether a child born without an anatomic part and with no cortical representation of that part will acquire an integrated activity through the process of cortical plasticity after a VCA. There is good evidence that cortical plasticity will provide integrative function. This has been shown in facial paralysis reconstruction in which the trigeminal nerve is used to reconstruct the seventh nerve.^{37,38} It has also been demonstrated in brachial plexus reconstruction in which the intercostal nerves are used

Table 65-1 Hand Transplantation Score System for Bilateral Hand Transplants

Date of Transplantation Follow-up (yrs)	2000		2000		2003		2003		2006	
	7		7		4		4		1	
	R	L	R	L	R	L	R	L	R	L
Appearance (0-15)	12	12	13.5	13.5	14	14	12.5	12.5	12.5	12.5
Sensibility (0-20)	18.5	19	17	17	16	19	9	10	12	12
Movement (0-20)	10.5	10.5	20	19.5	15	16.5	14.5	15	14	13.5
Psychological and social acceptance (0-15)	15	15	14	14	15	15	13	12	14	14
Daily activities and work status (0-15)	15	13	15	15	7	7	8	5	7	6
Patient satisfaction and general well-being (0-15)	15	15	15	15	11	11	6	6	6	6
TOTAL	86	84.5	95	94	78	82.5	63.5	60.5	65.5	64

L, Left hand; R, right hand.

The Hand Transplantation Score System evaluates six aspects with different weight for a total of 100 points: appearance (15 points), sensibility (20 points), movement (20 points), psychological and social acceptance (15 points), daily activities and work status (15 points), and patient satisfaction and general well-being (15 points). A total result of 81 to 100 points is graded as an excellent outcome, 61 to 80 as good, 31 to 60 as fair, and 0 to 30 as poor.

to power elbow flexion.³⁹ In a case of conjoined twins, one of whom survived, the surviving twin underwent a lower extremity transplant of her twin sister's leg. She had no cortical representation of the leg preoperatively. Because of cortical plasticity, she developed integrative function after the transplant. This was documented clinically and by MRI.³⁹⁻⁴¹

Thus, although we do not know for sure, we anticipate that with the aid of cortical plasticity, children who are born without parts and never had cortical representation may be suitable candidates for a VCA. Thus the lack of cortical representation of a missing part at birth should not necessarily preclude the possibility of transplantation and a worthwhile functional outcome.

The Effect of Immunosuppression in Children

Growth and Development

Children who receive solid-organ transplants must continue immunosuppressive therapy for life. Several studies have shown that immunosuppression does not impair growth.^{42,43} Many patients with end-stage renal disease have impaired growth potential and undergo catch-up growth after a kidney transplantation.^{42,43} Similarly, in liver transplantation patients, growth does not seem to be impaired with the use of long-term immunosuppressants.

Assessing growth and development can be difficult in patients with chronic disease. The studies on heart transplants in infants may provide better evidence. Studies by Hirsch et al⁴³ at Washington University and by Chinnock et al⁴⁴ at Loma Linda University showed normal growth and development in these children, despite immunosuppressive therapy.

The current thought is that growth and development alteration after a pediatric organ transplantation are related to long-term corticosteroid use.⁴⁵ Current efforts are aimed at reducing steroid use to low-dose levels, alternate-day dosing, or even to none at all. Reducing rejection episodes on this basis is critical, because steroids are often reintroduced or dosing increased to combat such episodes.

Lymphoproliferative Disease

Immunosuppressive therapy does not seem to alter growth or development in children. However, does the incidence of lymphoproliferative disease increase over time? The renal transplant data on this topic are excellent, specifically data from the North American Pediatric Renal Trials and Collaborative Studies.⁴⁶ In more than 10,000 transplants, the incidence of lymphoproliferative disease was 2.33%, and most occurred after 10 years. This relatively low rate is anticipated to become even lower with the newer immunosuppressive drugs. However, the incidence varies with the type of organ transplanted; kidney transplants have the lowest incidence, and intestinal transplants have the highest.⁴⁷ Young children may be more susceptible, because they may not have not been exposed to the Epstein-Barr virus; they are five times more likely to develop post-transplant lymphoproliferative disease.⁴⁷ Thus this disease is a concern in young children with long-term immunosuppression, particularly those who are Epstein-Barr virus seronegative, emphasizing the need for a broad-view risk-benefit analysis.

Malignancy

Long-term immunosuppression can increase the risk for other malignancies, including skin cancers in children, particularly malignant melanoma and the virally mediated Kaposi sarcoma.⁴⁷

Hypertension

Hypertension is a common sequela to immunosuppression therapy in children.^{48,49} It not only increases the risk for cardiovascular disease, but can also contribute to renal dysfunction. The causes are varied and seem to be dependent on the agents given, emphasizing the need to minimize immunosuppression (particularly corticosteroid).⁵⁰

Metabolic Alterations

As in adults, many children taking long-term immunosuppressants develop dyslipidemia and diabetes mellitus.⁴⁹ Both can increase the risk for cardiovascular disease and have been implicated in allograft vasculopathy.^{50,51}

Renal Failure

Even in nonrenal transplant recipients, renal function can decline with long-term immunosuppression.^{50,51} This ranges from mild nephrotoxicity to total loss of renal function, necessitating dialysis or renal transplant.^{50,51} The causes are multifactorial, including immunosuppressive drugs (especially tacrolimus), nephrotoxic antibiotics, hypertension, and poor allograft function.^{50,51}

Infection

Infection is the leading cause of mortality in pediatric transplant recipients.^{52,53} It can originate in the community, the hospital, and the donor organ, or it may be a reactivation of a previous viral infection. The risk is greatest immediately after transplantation, when immunosuppression is greatest to reduce the likelihood of acute rejection. This risk decreases over time but is a lifelong concern. Infants and young children are at an even greater risk for infection. They have a naive immune system that may not have developed antibodies to certain microbes, they may not have completed their vaccination series, and they may not have been exposed to some viruses such as cytomegalovirus, Epstein-Barr virus, and herpes virus. Transplant recipients should be appropriately immunized, informed of the importance of avoiding potentially infective situations, and able to begin broad-spectrum antimicrobials at the first sign of infection.

Immunosuppression is a necessary evil in the field of transplantation. However, the following steps can be taken to minimize its adverse effects:

- Avoiding or treating infection early
- Reducing or eliminating long-term corticosteroid use
- Minimizing the immunosuppressive drug regimen
- Carefully monitoring for the potential malignant and metabolic consequences

Ethical Concerns in Children

Although VCA is technically feasible, the ethical issues are considerable, particularly in pediatric patients.^{16,54,55} Several major factors require consideration.

Risk-Benefit Analysis

The first concern is a risk-benefit analysis. Hand and facial transplantation are not lifesaving but rather offer a chance to improve lifestyle. Therefore, a patient's quality of life benefit should be evaluated. A recent study showed that facial transplantation can add up to 20 quality-adjusted life-years.⁵⁶ Hand transplantation in adults has been shown to lead to functional improvement.⁹ The patients and families must be able to endure the surgery, the postoperative rehabilitation, and the long-term, lifelong immunosuppression. This becomes more complex when the consent process involves a substitute decision-maker. Parents are often conflicted in their desire to help their child and evaluate the risk-benefit ratio. Because the future of VCA in children is unknown, this process is even more complex. Will the allograft deteriorate with time and need to be repeated? What are the implications of this for face transplant patients, whose identity will be altered yet again? We know from solid-organ transplantation that compliance in adolescence is often a problem. Will this be the case in VCA patients, and will allografts be lost because of noncompliance by teenage recipients?

Long-term complications of immunosuppression are unknown. Will children develop kidney failure or skin malignancies, which are known to be much more aggressive in the immunosuppressed population. In evaluating the risks versus benefits, we must be very open-minded about these unknowns. As noted previously, the growth of a transplant may not be normal, its ultimate fate is uncertain, and an acceptable exit strategy may not be available should complications arise.⁵⁷ In children, issues of personal identity and social integration are highlighted and compounded because of the lifelong risk of immunosuppression therapy for a nonlifesaving procedure.

Informed Consent

The second ethical issue is informed consent. In some jurisdictions that have set no age of consent, decisions regarding the ability of a child to act autonomously are made on a case per case basis. In many cases, the parents make the decision, which could potentially lead to future resentment from their children. The issue of informed consent is also relevant to donors and their families. Generally, adult patients and parents consenting to donate might appreciate assurance that the organs will be used appropriately. The outcomes of VCA in children are uncertain, and such an assurance cannot be provided. Furthermore, donating a child's face involves an emotional component, and grieving parents might find this especially difficult.

Personal Identity

Another ethical issue to consider is personal identity. This pertains in particular to face transplantation in pediatric patients. A new appearance might affect a child's psychological, mental,

emotional, and social well-being.⁵⁸⁻⁶³ This will influence the selection of candidates as they pass through development stages at different assessment times.⁶⁴⁻⁶⁸ The contribution of psychological health before and after trauma becomes very complex in this context.

Utility and Equity

Concerns regarding utility and equity need to be addressed in any discussion of ethical issues regarding VCA. The usefulness of the part and its benefit to the child must be clearly explained, including the risks, both short-term and long-term. A transplant is a most-valuable entity and must be offered to potential recipients in an equitable fashion. Proper processes must be in place to allocate this precious resource fairly and to those most in need.

INDICATIONS FOR PEDIATRIC VASCULARIZED COMPOSITE ALLOTRANSPLANTATION

Currently, we describe two broad categories of children who will undergo a VCA: (1) those who have begun or are about to begin immunosuppression to support a solid-organ transplant and (2) those who require immunosuppression for a VCA.

Patients Who Have Begun or Are About To Begin Immunosuppression To Support a Solid-Organ Transplant

For patients who have begun or are about to begin immunosuppression to support a solid-organ transplant, the risks of immunosuppression are not weighed, because it will be required for the solid-organ transplant anyway. The risk of the actual surgery, its consequences, and its benefits can be independently evaluated with much less attention given to the effects of immunosuppression. Some risks may be increased with an additional allogeneic load, but the long-term effects of the immunosuppressive regimen should be about the same as those of a solid-organ transplant alone.

For children already on a balanced, stable immunosuppressive regimen, this is the best scenario. The first pediatric VCA was recently carried out under these circumstances. Zion Harvey had a devastating infection as a toddler and lost all four limbs and the function of both kidneys. However, he survived and, after receiving a kidney transplant from his mother, lived a restricted life as a quadramembral amputee. He was treated by the team at the University of Pennsylvania in Philadelphia, which had previously treated a young woman who was a quadramembral amputee. She had a remarkably good outcome. They studied Zion carefully and concluded that he would be an excellent candidate for upper extremity transplantation. He was listed for transplantation, and the actual surgery was carried out in July 2015. The early follow-up shows successful revascularization (Fig. 65-12; see Fig. 65-7) and we await reports on the functional outcome.

This 8-year-old boy is the first child to undergo a VCA. A team of 40 carried out the surgery at The Children's Hospital of Philadelphia under the leadership of Dr. Scott Levin. This bilateral hand transplant will change this boy's life dramatically, with minimal added immunosuppressive burden, because he had previously undergone a kidney transplant. However, even with immunosuppression under way to support a solid-organ transplant, differences exist for the various types of VCA. An upper extremity transplant, for example, is readily reversible should it prove nonfunctional or undergo rejection for whatever reason. We do not know the longevity of a VCA, and this may be particularly relevant in a child. A nonfunctional or rejected upper extremity can be amputated and the pretransplant state nearly reestablished. The situation is quite different, however, for a face transplant or an abdominal wall transplant patient. Failure of the allograft and removal of the transplant would be very difficult, with significant morbidity, and potentially fatal.

Fig. 65-12 Zion Harvey is the first pediatric VCA recipient. At 8 years of age he underwent a double-hand transplant. The early reports are most encouraging. (Courtesy of Children's Hospital of Philadelphia.)

Immunosuppression Is Required Specifically for Vascularized Composite Allotransplantation

Although a VCA is not a lifesaving procedure, it can be enormously life enhancing. In this situation, in children who undergo immunosuppression specifically to support a VCA, the risks and long-term effects must be worthwhile. This is a delicate balance that requires weighing all of the issues discussed previously, such as growth and function of the allograft, the effect of immunosuppression in children, and the ethical concerns. Presently, such scenarios would be unusual, but nevertheless worthy of consideration. The scenarios can be categorized according to the type of VCA (Fig. 65-13).

Face Transplantation

Facial trauma is very common in children and can occur from physical injury, animal bites, and surgical intervention. Even with extensive trauma, our reconstructive techniques can produce excellent or acceptable results in most patients. Occasionally, however, it is impossible to achieve the desired results in children with severe midface injuries and extensive soft tissue or even bony damage. A VCA may be an option in these extensive central facial injuries.

Most congenital facial anomalies are reconstructible to an excellent or acceptable degree. However, some rare craniofacial defects involving the central part of the face are very difficult to reconstruct adequately, including some of the rare craniofacial clefts and the severe forms of Treacher Collins syndrome and hemifacial microsomia.⁶⁹ Consideration of a VCA is warranted for other rare central facial deficiencies such as arhinia and those that result from the destructive processes of massive midface hemangiomas, vascular malformations, and neurofibromatosis.

Tracheolaryngeal Transplantation

In patients with severe laryngeal clefts and loss of the stability of the laryngeal and tracheal rings, providing a secure, reliable airway and the anatomic structures required for voice production may not be possible. Laryngeal transplantation may play a role in these rare, selected cases of congenital stenosis, tracheobronchomalacia, and laryngeal clefts, where conventional reconstruction fails to provide what is needed.

Fig. 65-13 Options for VCAs based on anatomic location.

Upper Extremity Transplantation

Children with congenital upper extremity anomalies function extremely well, compared with those who have similar, but acquired, anatomic deficiencies. Thus the indications for transplantation are more common in the group with acquired deficiencies. Traumatic injuries can result from trauma, surgery, or sepsis. Congenital anomalies that may be considered for a VCA include transverse arrest, amniotic band syndrome, and the extremes of overgrowth or vascular malformations. The factors to consider regarding suitability for a VCA include the functional impairment caused by the trauma or anomaly, bilaterality, the ineffectiveness of prosthetic use, and the overall benefit to a particular patient's quality of life.

Abdominal Wall Transplantation

Congenital anomalies of the gastrointestinal system can usually be reconstructed to an adequate degree. However, in rare circumstances the abdominal wall is absent, destroyed by an infective process or surgical intervention, and will not adequately support the abdominal organs. This can

occur with severe gastroschisis or with necrotizing enterocolitis. An abdominal wall transplant may be an option. This situation is most common in patients who also require an intraabdominal transplant.

THE FUTURE

VCA in children is an emerging field. Children who are already taking immunosuppressants and those who will require immunosuppressants for solid-organ transplantation may be candidates for a VCA for absent functionally significant anatomic parts. For children who do not take immunosuppressants, potential indications for a VCA include upper extremity loss, extensive mid-face and lower face deficits, abdominal wall deficiencies without adequate abdominal organ support, and extensive laryngotracheal deficiencies. These may be congenital or acquired through trauma, disease, or surgery.

VCA in general is an evolving area of surgical intervention. New indications are proposed, improved immunosuppressants are trialed, and a better understanding of infection control emerges. It is only a matter of time until these procedures are part of reconstructive surgeons' armamentarium for treating complex pediatric patients, providing opportunities for reconstruction never before possible.

KEY POINTS

- The history of VCA is a fascinating journey through medical history.
- The science of VCA is complex and becoming more complex with time.
- A transplant in children will grow and function in a manner similar to a replant or a free tissue transfer.
- Surgeons need to understand the effects of immunosuppression on growing children; in appropriate circumstances these should not be a barrier to a VCA.
- The ethical issues of risk-benefit ratios, informed consent for young children, personal identity in patients with visible transplants, utility, and equity need to be discussed openly, fully, and to the best of our knowledge.
- The indications for a VCA in children vary depending on whether immunosuppression has begun or is about to begin to support a solid-organ transplant and whether immunosuppression is required specifically to support the VCA.
- Options for potential VCA in children include the upper extremities, the face, the abdominal wall, and the tracheolaryngeal complex.
